In my paper "On Lightning Conductors, and Accidents by Lightning," read before this Association in 1878, I cited two cases of damage to buildings provided with lightning conductors, which, on a careful investigation of the facts, showed that the lightning rods were inefficiently erected. On the present occasion I wish to bring under the notice of the Association a few cases which have come under my own observation of damage resulting to buildings which had lightning conductors attached. The adducing of such cases furnishes the best argument, I imagine, not only for a record being kept of all accidents; but of a regular inspection of buildings which have lightning conductors attached to them.

On the 10th of October, 1878, a furniture repository situated at the back of Victoria Station, Westminster, was struck by lightning, although a conductor was attached to the building. The warehouse, which is built of brick, is 110 feet, by about 80 feet wide, the roof is flat and covered with lead. At the south-east corner, a slate covered tower with four feet of iron cresting rises to the height of 20 feet above the roof. To this ornamental iron-work a solid copper band lightning conductor $\frac{3}{4}$" broad × $\frac{1}{8}$" thick, and weighing ·43lbs. per foot was attached. A terminal made of $\frac{3}{4}$" dia. copper tube, with three discharging points 6 inches long, screwed into the rod 3 inches from the top, rose three feet above the iron cresting. The rod was attached to the ironwork by means of copper wire, and the band to the slates and brick work by gun metal clips. The copper was of very good quality, having a conductivity of 92·00 per cent. The electric discharge fell on the point of the lightning conductor, bending it, driving out two of the discharging points and twisting the third. The iron cresting was shattered, and considerable damage done to the tower. Part of the discharge was, no doubt, carried off from the lead roof by the rain water pipes, which were in metallic communication with it. On testing the conductor shortly after the accident, I got no deflection of the galvanometer needle, and on opening out the earth terminal found the conductor carefully insulated in concrete.

On the 10th of June last, lightning struck the point of the conductor at St. Mark's Church, Skelton, slightly bending it; but did no further damage. The conductor was made of $\frac{3}{8}$" dia. copper rope, and had a conductivity of 52·50 per cent. On testing the conductor, while rain was falling, I found the resistance to be 600 ohms. The conductor was buried 9" among bricks, lime, &c., and carried 15 feet from the building.

On Saturday, the 26th of June, 1880, a heavy thunderstorm passed over South Lambeth, the lightning doing considerable damage to All Saints' Church. A stone cross 4 feet high stands on the apex of the west gable of this building, and another of similar size stood 92 feet 6 inches from it on the east end of the nave, a ridge of red tiles separating them. A $\frac{3}{8}$" dia. copper rope conductor consisting of 40 wires was attached to the cross on the west gable, a 5 feet point made of copper tube rising 18 inches above it. On the afternoon of the 10th lightning was observed to strike the point of the conductor, then dart to the stone cross on the east nave, throwing it down and injuring the roof of the north aisle. On testing the conductor a few days after the building was struck I found the lightning rod had no "earth" whatever, the rope being simply stuck 2 inches in loose rubbish. The copper was very impure, the conductivity being only 32·10 per cent., or about double that of iron.

* The electromotive force of the chloride of the silver cell is 1·03 volt.
† Read before Section A of the British Association at Swansea, Aug. 27, 1880.

84

In July last about half-past five in the morning, lightning struck one of the chimneys of Normanhurst Court, near Battle, Sussex, notwithstanding a lightning conductor was attached to it. There were two lightning conductors on the buildings. One on an octagonal tower, which rises from the S.W. angle, having a balcony and a lofty stone spire, about 120 feet high, the other on the S.E. chimney, which was struck, about 126 feet distant from the tower. The lightning conductors consisted of twelve copper wires, 15 B.W.G. woven into the form of a band an inch broad, and weighing ·36lb. per foot. The air terminal, which rose 3 feet above the chimney coping, consisted of an iron point 12 inches long, covered with a composition which on scraping appeared to be lead, this was attached by means of a coupling joint to a copper tube 6 feet long, and weighing ·28lb. per foot. The copper band was connected to the rod by another coupling joint. The chimney coping consisted of eight ornamental stone pinnacles 3 feet high and 2 feet square at the base. The terminal rod was placed on the centre of the chimney—and insulated from it. The lightning discharge struck the chimney, destroying three of the pinnacles, which falling through the roof below did considerable damage. The air terminal was bent, and the composition on the point melted 3 inches. The wires near the terminal point were likewise partly fused, and on taking out one wire 25 feet below the terminal rod, I found it so irregular in thickness that it had to be redrawn before the conductivity could be determined. On testing the earth terminal I could get no deflection of the galvanometer needle, the conductor being buried in dry earth within a stone wall 8 feet above the fosse, or asphalted area. The conductor on the tower had "good earth." The conductivity of the copper was 80·5.

From the instances quoted, it is evident that it is not sufficient merely that rods of copper should be attached to a building, but it is necessary that once put up they should be regularly inspected to see if they are in good order, so as to be really efficacious. That this is rarely done is one of the main reasons why accidents by lightning occur in places nominally protected by conductors. It is, perhaps, not too much to assert that at present not one in a thousand of our public buildings in England is regularly tested.

There can be no manner of doubt that in the matter of lightning conductors they manage things better on the other side of the Channel than with us. The French Government are in the constant habit of consulting the most eminent scientific men on the subject of protecting public buildings against the destructive influence of lightning. There is scarcely an instance in which a British Government ever did such a thing. It is true the Houses of Parliament had lightning conductors erected upon them at a very great cost and under scientific advice; but all who understand the subject practically agree in saying that it is very doubtful whether the magnificent pile of buildings in which our legislators assemble is really—that is efficiently—protected. At all events I understand the earths have never been tested since the conductors were erected in 1852. That the Victoria Tower should have been struck in June, 1868, and slightly damaged tends to show that the conductors at that time were not in an efficient state.

From the examination I have made I am pretty correct in stating that one-half of our cathedrals and three-fourths of our churches have not even nominal protection. For all that science has done the Queen might any day be killed in her apartments at Windsor Castle, the Prince of Wales in Marlborough House, and the Prime Minister in Downing-street. To see the difference between England and France in this respect, one has but to cross the Channel between Dover and Calais. At Dover there are huge barracks of great length, on the top of high hills, exposed to the full fury of storms sweeping across the Channel, and the few conductors to be found upon them at long intervals are certainly not numerous enough for efficient protection against lightning, and their efficiency has never, so far as I can learn, been tested. The contrast in this respect on crossing the Channel is of the most striking. At Calais, the Hotel de Ville, in the Grand Place, literally bristles with lightning conductors, and so all the churches and chief buildings in the town. The same all over France, Germany, and Belgium. Without slavishly imitating our scientific neighbours, we might yet bestow some of the care they do upon the protection of our property as well as of our lives against the terrible effects of the electric force.

During a recent thunderstorm at Hamburg the British Consul, Mr. Pogson, observed the phenomena of St. Elmo's fire playing above the tip of the spire of a church three-quarters of a mile away. Twenty times within one hour a pale-bluish ball of light resembling in tint the flame of burning potassium was seen. It appeared to be spherical in form, and from three to six feet in diameter. It seemed to hover above the spire without touching it, and lasting about forty seconds at each time of appearance. 37

ELECTRICIAN, SEPTEMBER 11, 1880.

CURIOUS FREAK OF LIGHTNING.—*Le Petit Marseillais* is answerable for the following:—"St. Etienne, Aug. 23. Last Thursday, during a violent storm, a young man was walking along the Richelandière road, having in his hand a carriage lamp, unlighted. Suddenly he experienced the sensation of a violent shock in his arm, and concluded that the lightning had either struck him or fallen close to him. But what was his astonishment to find that his lamp had been lighted! Several persons who were behind him on the road observed this curious phenomenon." 37

Mining Press Oct 16 1880

THE COURSE OF A LIGHTNING FLASH.—Prof. Tait, of Edinburgh, insists that when people think they see a lightning flash go upward or downward they must be mistaken. The duration of a lightning flash is less than the millionth part of a second, and the eye cannot possibly follow movements of such extraordinary rapidity. The origin of the mistake seems, he says, to be a subjective one, viz., that the central parts of the retina are more sensitive, by practice, than the rest, and therefore that the portion of the flash which is seen directly affects the brain sooner than the rest. Hence a spectator looking towards either end of a flash very naturally fancies that end to be its starting point. 37

Report of the Committee on Erratic Blocks, presented by the Rev. H. W. Crosskey. (Abstract.)—Although the destruction of erratic blocks is proceeding with considerable rapidity, the Committee were able to report the discovery and preservation of some important specimens.

One of the most remarkable blocks of Shap granite yet observed is described by Mr. J. R. Dakyns at Seamer Station, near Scarborough. It measures roughly 5 ft. 8 in. × 4 ft. 10 in. × 4 ft. 3 in., and was fairly imbedded in gravel, forming the summit of a well-marked terrace 225 feet above the sea-level. This boulder is specially interesting in that it is the only boulder of Shap granite in the neighbourhood whose position in the beds is known; and this position shows that at the age assigned to the gravels (which is a comparatively recent one) icebergs must have been floating about. It has been preserved in the garden of the Station House.

The report records particulars of boulders discovered in the neighbourhood of Urmston, near Manchester, and also of a large number both of isolated boulders and groups of boulders observed in Leicestershire by Mr. J. Plant.

Mr. Pengelly furnishes a very interesting part of the report in an account he gives of some transported blocks and accumulations of blocks which he has observed in South Devon, the transposition of which it does not seem altogether possible that the action of water alone could have effected. A block of greenstone occurs in the village of Kingston, South Devon, measuring 4 × 2 × 2 feet, and weighing upwards of a ton. There is a mass of greenstone figured on the map of the Survey, extending to about a mile west-north-west of Kingston, where it makes its nearest approach to the village. Blocks of quartzite have been found in great abundance in the parishes of Diptford and Morleigh. They can be traced to their source on the higher levels of the neighbourhood; a bed of quartzite identical in character with the travelled blocks being interbedded conformably with the ordinary slaty Devonian rocks of the district. There can be no doubt that the blocks have been transported from south to north, and from higher to lower ground. The gradient, however, is very slight, and as almost all the blocks are very angular as well as large, it is difficult to suppose that their transportation was the result of nothing more than running water.

A block of greenstone occurs near Diptford Court, weighing fully 1·75 ton. A mass of igneous rock apparently of the same kind is found at a distance of five miles due south of the boulder, and another about the same distance north.

The blocks locally termed in South-Western Devon "Whitakers", are described in the report. They are composed of white opaque quartz, having in some cases a laminated structure, and traversed occasionally with veins and crystals of the same material. That the blocks have travelled a considerable distance cannot be doubted; and that their transportation was not effected by the action of water only appears proved. The blocks are all more or less rugged and sub-angular, although without any decided traces of glacial polish or scratches. They occur most plentifully on the higher ground.

They have been so largely utilised by the farmers and for artificial rockeries that it is to be feared, unless care is taken to prevent it, those now remaining on the spots they have so long occupied undisturbed may altogether disappear.

The report concluded with an appeal to local observers to report upon the erratics still unrecorded before the work of destruction is completed, and evidence throwing light on difficult problems of glacial geology is destroyed.

Fortnightly Review 1880 85

Report on the Exploration of Caves in the South of Ireland, by Prof. A. Leith Adams. Includes a Report by Mr. R. J. Ussher.—Describes caves at Carrigan Gower, four miles south of Middleton. Stalagmite floor on sandy clay; beneath the stalagmite was much charcoal, the roof had an opening to the surface, down which much kitchen rubbish had been thrown, associated with hammer stones, flint flakes, iron implements, and remains of recent animals. A report was read on the implements, by Mr. R. Day, which are of no great antiquity; one piece of pottery was believed to have a Roman (capital) letter inscription.

Report on the Carboniferous Polyzoa, by W. G. R. Vine.—Discusses the character of the genus and species and the views held on them by the earlier workers, and after a comparison of the specific forms he relegates to each of these the precise genera to which they belong.

Report on the "Geological Record," by Mr. W. Whitaker.—Four volumes have been published, each of which gives an abstract of all geological work done throughout the world, for one year; they contain an average number of 20,000 entries in each volume.

Sixteenth Report of the Committee appointed to Explore Kent's Cavern, by Mr. Pengelly.—The deposits passed through in the cavern were:—

Iron and Bronze.		BLACK MOULD. Roman Remains (Ovine).
Palæolithic	Newer Type.	GRANULAR STALAGMITE, 5 feet. Extinct Animals.
		CAVE EARTH. Extinct Animals. (Hyæna).
	Rougher Type.	CRYSTALLINE STALAGMITE, 12 feet. (Bears).
		BRECCIA.

Work commenced in March, 1865, by excavating down to 4 feet throughout the whole cavern; finished in November, 1879, the floor had at that time been so excavated, at a cost of 1,850*l.* to the Association. A further grant was then given to lay bare the limestone floor; and subscriptions from private sources amounted to 51*l.* received, which enabled the base of the cave deposit to be excavated for a length of 132 feet. Occasionally stalagmitic fragments occurred on the base of the breccia, resting on the rock. On June 19, 1880, the work was suspended, it having only yielded seventeen finds—amongst them a flint nodule, which had not been touched by the implement maker—which are of greater rarity. Archæological finds were more numerous than remains of animals; the implements correspond to those of the oldest river gravels in type. Referred to the good work done by Mr. George Smerdon, the foreman of the workmen during sixteen years, who has become crippled with rheumatism, brought on by excavation of the work, and suggested the desirability of raising subscriptions to purchase for him an annuity of 10*l.* a year.

Report of the Committee, consisting of Mr. James Heywood, Mr. Shaen, Mr. Stephen Bourne, Mr. Wilkinson, the Rev. W. Delaney, and Dr. J. H. Gladstone (Secretary), appointed for the purpose of reporting whether it is important that H.M. Inspectors of Elementary Schools should be appointed with reference to their ability for examining in addition to other matters.—The Committee nominated at Sheffield for the purpose of considering "whether it is important that H.M. Inspectors of Elementary Schools should be appointed with reference to their ability for examining the scientific specific subjects of the Code in addition to other matters," have received a considerable amount of evidence upon the subject, and beg to report as follows:—

1. It has come to their knowledge that the teaching of the scientific specific subjects is practically discouraged by the incapacity of many of H.M. Inspectors to examine in them.

2. This incapacity is explained by the fact that the Inspectors are not generally chosen so much for their fitness to judge of such educational work, as on account of their high scholarship, or through political patronage.

3. In the opinion of this Committee there might be an examining body for H.M. Inspectors, composed of three of the most experienced of the present senior Inspectors, associated with a similar number of the Science Examiners of the Science and Art Department. The examination should be thrown open to elementary teachers, and the candidates might be tested in the practical work of examination in one of the Central Elementary Schools in London.

4. The Committee believe that the opening of the Inspectorship to fully qualified elementary teachers would tend to raise the *esprit de corps* of the profession, and improve the character of both inspector and teacher.

5. The Committee are further of opinion that while a university degree may be fitly regarded as a test of scholarship, it is not a test of the particular qualifications for an examiner, and therefore is not sufficient in itself to guarantee the holder thereof as worthy the position of Inspector. There appears to be no reason why academical honours should be made an indispensable condition of appointment.

6. The Committee recommend that a memorial be presented to the Lords of the Committee of Privy Council on Education embodying the above conclusions.

Report of the Committee, consisting of Dr. Pye-Smith, Prof. M. Foster, and Prof. Burdon Sanderson (Secretary), appointed for the purpose of investigating the Influence of Bodily Exercise on the Elimination of Nitrogen (the Experiments to be conducted by Mr. North).—During the past year four series of preliminary experiments, each of several weeks' duration, have been made by the Committee on the subject, the expenses of which have been met from other funds. In the course of these experiments unexpected difficulties have been encountered relating to method. The most serious of these difficulties having now been for the most part overcome, we are in a position to proceed with our inquiries next winter, and have therefore to request that the sum of 50*l.*, previously granted to us, may again be placed at our disposal.

...d of time almost inconce... short, and that the full effect of on the eye is not produced until after the lapse of a considerable ...n of a second. Professor Swan has estimated this interval at one-tenth of a second; and he has proved that the apparent in... of illumination for shorter intervals is nearly proportional to ...ration.

4. If June, July, August, or December be *warm*, the next month will probably be a warm one also.

5. Two months, June and July, tend, when very *dry*, to be followed by dry ones. On the other hand, a dry August indicates the probability of a *wet* September.

6. A *wet* December is apt to be succeeded by a wet January.

In addition to the foregoing, there are also a few instances in which the rainfall of certain months appears to be definitely related to antecedent extremes of temperature, and *vice versâ*. Thus

7. If August or September be *warm*, the ensuing September or October inclines to be wet. If, on the other hand, September or November be *cold*, the succeeding October or December is likely to be a dry month.

8. If February, June, or July be very *dry*, the next month has a strong tendency to be warm.

9. If January, March, or April be *wet*, we may also expect the next month to be a warm one. But a wet May or July gives a strong probability of cold weather in June or August respectively.

Preece 31

Mr. W. H. Preece read a paper *On the Best Form to give to Lightning Conductors*. The question was whether the lightning conductor should be a solid rod, or tubular, or flat. Snow Harris, Prof. Henry, M. de Melsens, and M. Guillemin advocated straps of great surface. Faraday strongly maintained that there was no advantage in strap or tube forms, as the surface does nothing in conducting the current. Mr. Preece had obtained the use of Dr. De La Rue's magnificent batteries, and had procured conductors of equal material, length, and weight, but differing in form. A condenser charged from 3,400 cells afforded a very powerful source of electricity, more than forty-two microfarads being thus available to produce an enormous spark. Experiments made by heating and deflagrating wires through the different conductors left no doubt that these discharges do obey the law of Ohm, and therefore that the additional surface of flat and tubular conductors is of no advantage in their conductivity.

Prof. Osborne Reynolds rather doubted the conclusions of Mr. Preece, on account of our not knowing the conditions under which the electricity passes from the air into the surface of the conductor. Prof. Ayrton thought the experiments should be tried with much greater difference of potential. The 3,000 cells would not produce a free spark of more than $\frac{1}{75}$ of an inch long, whereas flashes of lightning might extend over miles.

Mr. Preece, in replying, pointed out that increased surface, though increasing its inductive capacity, did not add to its efficiency, which depended only on its conductivity.

Mr. Preece also communicated an observation on the peculiar behaviour of copper wires. Very powerful discharges of electri- in an electric... found to increase th...

From the examination I have made I am pretty correct in stating that one-half of our cathedrals and three-fourths of our churches have not even nominal protection. For all that science has done the Queen might any day be killed in her apartments at Windsor Castle, the Prince of Wales in Marlborough House, and the Prime Minister in Downing-street. To see the difference between England and France in this respect, one has but to cross the Channel between Dover and Calais. At Dover there are huge barracks of great length, on the top of high hills, exposed to the full fury of storms sweeping across the Channel, and the few conductors to be found upon them at long intervals are certainly not numerous enough for efficient protection against lightning, and their efficiency has never, so far as I can learn, been tested. The contrast in this respect on crossing the Channel is of the most striking. At Calais, the Hotel de Ville, in the Grand Place, literally bristles with lightning conductors, and so all the churches and chief buildings in the town. The same all over France, Germany, and Belgium. Without slavishly imitating our scientific neighbours, we might yet bestow some of the care they do upon the protection of our property as well as of our lives against the terrible effects of the electric force.

$\frac{3}{8}$-inch by $\frac{1}{2}$-inch copper band lightning-conductor and a tube of $\frac{3}{4}$-inch diameter rising above the iron crestings on the tower. The lightning shattered the cresting and bent the point of the lightning-rod, besides doing other damage to the building. On testing, the author found the resistance very great, and on opening out the earth-terminal found it imbedded in concrete.

On June 26 last, lightning struck All Saints Church, Lambeth, doing considerable damage, although there was a $\frac{1}{2}$-inch diameter copper-rope conductor on the west gable, with a copper tube rising 18 inches above. A stone cross about 50 feet from the conductor was thrown down, injuring the roof of the north aisle. On testing the conductor, the author found that it had no "earth" whatever, the rope being simply placed in 2 inches of loose rubbish. The copper was of very inferior quality; conductivity being 32·10 per cent., or about double that of iron.

The author quoted also a few cases from his recent work on "Lightning-Conductors, their History," &c.:—

In August, 1878, the Powder Magazine at Victoria Colliery, Burncliffe, Yorkshire, was struck by lightning, though furnished with a conductor, 13 feet above the building, and terminating in 13 feet of clayey soil. The building was blown to pieces. On testing the conductivity of the copper, it was found to be 39·2, instead of 92 to 94 per cent. The conductor was insulated from the building and from a large iron door, which it ought not to have been.

The author concludes from this evidence that it is not sufficient merely that rods of copper should be attached to a building, but it is necessary that after being fixed they should be regularly inspected, to see if they are in good order, so as to be really efficacious.

Sir Wm. Thomson gave a communication *On a Method of Measuring Contact Electricity*. Sir W. Thomson had devised this method at the time when Hankel published his results in 1861. A method identical with it had lately been described by M. Pellat, and consisted in employing a small electromotive force in connection with a dividing resistance slide, to give a counterbalancing electromotive force to that produced by contact. 6

Sir W. Thomson next described *A Method of Determining without Mechanism the Limiting Steam-Liquid Temperature of a Fluid*. This was a simple apparatus, consisting of a closed glass tube containing liquid sulphurous acid filled to a sufficient height to insure that the liquid in the lower half will expand to the top. Prof. W. Ramsay criticised the proposal, and stated that he had found an apparatus in which a screw was employed to produce increase of pressure instead of using the expansion of the liquid itself. With this apparatus he had repeated Andrews' research on a large number of substances.

Mr. G. F. Fitzgerald read a paper *On the Possibility of originating Wave-disturbances in the Ether*. This was a mathematical paper, in which, by comparing the equations of Maxwell's theory of the propagation of electric action through a medium with those of direct action at a distance, he deduced the conclusion that electric currents and systems cannot originate in the ether such disturbances as those of light.

Mr. R. M. Shida gave an account of *A New Determination of the number of Electrostatic Units in the Electromagnetic Unit*. The value V of this ratio he deduced was $294·4 \times 10^8$. 6

M. Wilfrid de Fonvielle exhibited his magneto-electric gyroscope, which has been already described in our pages.

M. Janssen sent a communication to the Section, which was read by the Secretary, upon his recent researches *On the obtaining Positive Photographs by Prolonged Exposure*.

Mr. Wiesendanger showed a new electromotor, which will be described hereafter in our pages.

Mr. Philip Braham exhibited an ingenious adaptation of lime-light for microscopic illumination, and also described a simple instrument for detecting polarised light.

On the Best Form of Magnet for Magneto Machines, by W. Ladd.—At the British Association meeting at Dundee in 1867, I made some remarks upon different forms of magnets, and exhibited these diagrams, showing, by the "lines of force" naturally arranged, the great superiority of the circular magnet where an armature is to be employed. 17

Since that time some thousands of that form of magnet have been made for medical, mining, and other purposes.

Some months ago, in conversation with M. Breguet of Paris, I showed him these same diagrams, and he was very much impressed with their importance; he has since then constructed a machine, using the Gramme armature, and with a smaller quantity of steel in the magnets he has made a far more powerful

Science

ON THE AURORA AND ZODIACAL LIGHT OF MAY 2, 1877.

37 Sept. 18

By Henry C. Lewis.

A simultaneous appearance of an aurora and the zodiacal light appeared on this evening, and a comparison between them is here given. The various changes of the aurora are given in detail. A remarkable feature was the formation of a bright streamer which maintained its position relative to the earth for nearly an hour. Meanwhile, the Zodiacal Cone, which was bright early in the evening had moved past the streamer and passed below the horizon. The streamer had remained, like the great pointer, fixed to the earth, and marking its motion, while the heavens revolved past it. This fact was conclusive evidence of the terrestrial character of the aurora and of the cosmical character of the zodiacal light. Another fact leading to the same conclusion was the character of their spectra. That of the zodiacal light was continuous, and that of the aurora was a line-spectrum—the former is such as would be given by sunlight reflected from matter in space; the latter would be given by an electric discharge through a gas.

The Course of a Lightning Flash.

Prof. Tait, of Edinburgh, insists that when people think they see a lightning flash go upward or downward they must be mistaken. The duration of a lightning flash is less than the millionth part of a second, and the eye cannot possibly follow movements of such extraordinary rapidity. The origin of the mistake seems, he says, to be a subjective one, viz., that the central parts of the retina are more sensitive, by practice, than the rest, and therefore that the portion of the flash which is seen directly affects the brain sooner than the rest. Hence a spectator looking toward either end of a flash very naturally fancies that end to be its starting point.

Engineer Sept. 24 1880. Gmon Oct. 9, 1880

Electric Storms.—The valley of the Missouri and other districts, which suffered so much from tornadoes, have been examined by Professor Tice, who has come to the opinion that the storms were of an electric nature. He arrived at this conclusion by the fact that the buildings which suffered most were those which were covered with zinc or other metallic roofing, while houses roofed with slate or tiles almost invariably escaped. The iron chimney of a factory was torn off and twisted about in a remarkable manner, while the rest of the building showed no trace of damage; and the same happened to the bell cupola of a large school, which, being made of sheet tin, was completely destroyed. The Professor also noticed that those trees which suffered from the storm were not injured particularly from the windward side, or bent in any direction by the storm, but that the whole of them were stripped of their leaves instantaneously like broomsticks, and that the bark presented an appearance as of scorching. 37

Some interesting particulars relating to the fact that in some tropical countries the electrical phenomena of the lowest atmospheric layer are much more marked than in temperate climates have been lately given by M. Amat from experiences in the Northern Sahara. Without insulating himself from the ground, he could often get sparks 0·03in. to 0·07in. by simply passing a pocket-comb through his hair or beard. This succeeded best in dry, hot weather, on return from a long excursion over arid plains, the most favourable time being in the evening from seven to nine o'clock. Some lower animals, and especially horses, present electric phenomena still more strikingly. On hot summer days, one sees on Arab horses long hairs diverging from the middle of the tail. Caressing the tail with the hand, a number of crackling sounds are heard, and, if it be in darkness, sparks are seen. The electricity liberated by the tail of horses M. Amat finds to be positive. Man, in direct communication with the ground, does not show such an accumulation of the electric fluid as the horse does, and friction is necessary to develope it. The horn of the horses' hoofs seems to act as an insulator. 37 Engineer Sept. 24 1880

Science. Nov. 27.

Intensity of Certain Phenomena of Atmospheric Electricity Observed in the North of the Sahara.—L. Amat has observed that in tropical countries the electric phenomena of the atmospheric stratum in contact with the soil are more distinct than in colder climates. 37

Stoddard's Review Dec 1880 85

THUNDERSTORMS.

Stoddard's review Dec, 1880

BY PROFESSOR TAIT.*

By far the most striking of the phenomena of a thunderstorm—at least if the storm come on during the day—is the extraordinary darkness. Sometimes at midday in summer the darkness becomes comparable with that at midnight, very different in kind as well as intensity from that produced by the densest fog. Objects are distinctly visible through it at distances of many miles, whether when self-luminous, or when instantaneously lit up by lightning. The darkness, then, is simply intense *shadow*, produced by the great thickness and great lateral extension of the cloud-masses overhead. Seen from a distance, the mass of cloud belonging to the storm usually presents a most peculiar appearance, quite unlike any other form of cloud. It seems to boil up, as it were, from below, and to extend through miles of vertical height. The estimated height of its lower surface above the ground varies within very wide limits. Saussure has seen it as much as three miles; and in one case noticed by De l'Isle it may have been as much as five miles. On the other hand, at Pondicherry and Manilla it is scarcely ever more than half a mile. Haidinger gives the full details of an extraordinary case, in which the thundercloud formed a stratum of only twenty-five feet thick, raised thirty yards above the ground. Yet two people were killed on this occasion. Other notable instances of a similar extreme character are recorded.

Careful experiment shows us that the air is scarcely ever free from electricity, even in the clearest weather. And even on specially fine days, when large separate cumuli are floating along, each as it comes near produces a marked effect on the electrometer. Andrews obtained by means of a kite, on a fine clear day, a steady decomposition of water by the electricity collected by a fine wire twisted round the string.

The next striking features are the flashes of lightning, which at intervals light up the landscape with an intensity which must in the majority of cases far exceed that produced by the full moon. To the eye, indeed, the flash does not often appear to furnish more than the equivalent of average moonlight, but it must be remembered that it lasts for a period of time almost inconce... short, and that the full effect of light on the eye is not produced until after the lapse of a considerable fraction of a second. Professor Swan has estimated this interval at about one-tenth of a second; and he has proved that the apparent intensity of illumination for shorter intervals is nearly proportional to the duration.

LIGHTNING CONDUCTORS.*

By Richard Anderson, F.C.S., F.G.S.

On the present occasion I wish to bring under the notice of the association a few cases of damage resulting to buildings which had lightning conductors attached, which have come under my own observation. The publishing of such cases furnishes the best argument, I imagine, not only for a record of all accidents, but of a regular inspection, a record being kept of that of buildings which have lightning conductors attached to them.

On the 10th of October, 1878, a furniture repository situated at the back of Victoria Station, Westminster, was struck by lightning, although a conductor was attached to the building. The warehouse, which is built of brick, is 110 ft. by about 80 ft. wide, the roof is flat and covered with lead. At the southeast corner, a slate covered tower with 4 ft. of iron cresting, rises to the height of 20 ft. above the roof. To this ornamental ironwork a solid copper band lightning conductor, 1 in. broad by ⅛ in. thick, and weighing 0·43 lb. per foot, was attached. A terminal made of ½ in. diam. copper tube with three discharging points 6 in. long, screwed into the rod 1 in. from the top, rose 4 ft. above the iron cresting. The rod was attached to the ironwork by means of copper wire, and the band to the slates and brickwork by gun metal clips. The copper was of very good quality, having a conductivity of 92 per cent. The electric discharge fell on the point of the lightning conductor, bending it, driving out two of the discharging points, and twisting the third. The iron cresting was shattered, and considerable damage done to the tower. Part of the discharge was no doubt carried off from the lead roof by the rain water pipes, which were in metallic communication with it. On testing the conductor shortly after the accident, I got no deflection of the galvanometer needle, and on opening out the earth terminal found the conductor carefully insulated in concrete.

On the 3d of June last, lightning struck the point of the conductor of St. Mark's Church, Skelton, slightly bending it, but did no further damage. The conductor was made of ½ in. diam. copper rope, and had a conductivity of 52·50 per cent. On testing the conductor, while rain was falling, I found the resistance to be 600 ohms. The conductor was buried 9 in. among bricks, lime, etc., and carried 15 ft. from the building. On Saturday, the 26th of June, 1880, a heavy thunderstorm passed over South Lambeth, the lightning doing considerable damage to All Saints Church. The building in question, the style of which partakes of the characteristics of the thirteenth century, consists of a nave 92 ft. 6 in. long, 25 ft. wide, and 36 ft. high to the plate level of the roof, a chancel 31 ft. long, 20 ft. wide, and 48 ft. to the ridge, also north and south aisles 13 ft. 3 in. wide. A stone cross 4 ft. high stands on the apex of the west gable, and another of similar size stood 92 ft. 6 in. from it on the east end of the nave, a ridge of red tiles separating them. A ⅝ in. diam. copper rope conductor, consisting of 40 wires, was attached to the cross on the west gable, a 5 ft. point made of copper tube rising 18 in. above it. On the afternoon of the 10th, lightning was observed to strike the point of the conductor, then dart to the stone cross of the east end of the nave, throwing it down and injuring the roof of the north aisle. On testing the conductor a few days after the building was struck, I found the lightning rod had no "earth" whatever, the rope being simply stuck 2 in. in loose rubbish. The copper was very impure, the conductivity being only 32·10 per cent., or about double that of iron.

In July last, about half-past five in the morning, lightning struck one of the chimneys of Normanhurst Court, near Battle, Sussex, notwithstanding a lightning conductor was attached to it. Normanhurst stands on high land, and commands a magnificent view of the whole channel from the South Foreland to Beachy Head. The buildings are constructed of hard blue stone, roofed with Broseley tiles; and are in the style of the age of Francis I. There were two lightning conductors on the buildings; one on an octagonal tower, which rises from the S. W. angle, having a balcony and a lofty stone spire, about 120 ft. high, the other on the S. E. chimney, which was struck, about 126 ft. distant from the tower. The lightning conductors consisted of 12 copper wires, 15 B. W. G., woven into the form of a band 1 in. broad, and weighing 0·36 lb. per foot. The air terminal, which rose 3 ft. above the chimney coping, consisted of an iron point 12 in. long, covered with a composition which on scraping appeared to be lead; this was attached by means of a coupling joint to a copper tube 6 ft. long, and weighing 0·28 lb. per foot. The copper band was connected to the rod by another coupling joint. The chimney coping consisted of eight ornamental stone pinnacles 3 ft. high and 2 ft. square at the base. The terminal rod was placed on the center of the chimney, and insulated from it. The lightning discharge struck the chimney, destroying three of the pinnacles, which, falling through the roof below, did considerable damage. The air terminal was bent, and the composition on the point melted 3 in. The wires near the terminal point were likewise partly fused, and, on taking out one wire 25 ft. below the terminal rod, I found it so irregular in thickness that it had to be redrawn before the conductivity could be determined. On testing the earth terminal, I could get no deflection of the galvanometer needle, the conductor being buried in dry earth within a stone wall 8 ft. above the fosse, or asphalted area. The conductor on the tower had "good earth." The conductivity of the copper was 80·5.

In my recently published work on "The History and Application of Lightning Conductors," the following cases among others are given:

On the 6th of August, 1878, lightning struck the powder magazine at the Victoria Colliery, Burntcliff, Yorkshire. At the time of the explosion the magazine contained about 2,000 lb. of gunpowder. The magazine was an oblong building of brick, 9 ft. long, 5 ft. wide, and 8 ft. high (internal dimensions), and it had a uniform thickness of three bricks. At the end was a heavy iron door, and at the other a lightning conductor, consisting of a copper wire rope seven-sixteenths of an inch in diameter. The point of the terminal rod was about 18 ft. above the top of the building, and a similar length was carried into the ground, and terminated in clayey soil at a depth of 8 ft. The conductor was fixed to a pole distant about 2 in. from the end of the building opposite to that in which the iron door was fixed. *It was not connected with the iron door in any way.* On testing the conductivity of the copper rope it was found to be only 39·2 instead of 93 or 94 per cent. The conductor should not have been insulated, but brought down the pole, carried along the roof down the iron door post, and so into the ground.

In August, 1879, lightning struck one of the pinnacles of the tower of Cromer Church, Norfolk, although on another pinnacle only 27 ft. 8 in. distant, a good copper conductor, having a diameter of ⅜ of an inch was placed. On testing the conductor by means of a galvanometer, I found it and the earth connection in thorough order. In this case, a point should have been placed on each of the pinnacles, and joined the main conductor.

In May, 1879, the steeple of the church at Laughton-en-le-Morthen was struck by lightning and damaged. The spire, 175 ft. in height, had attached to it a thin tube made of corrugated copper, about ⅝ of an inch in external diameter, and ⅛ internal; the copper being 1-32 of an inch in thickness. It was made in short lengths joined together by screws and coupling pieces, but there was no metallic contact whatever between the pieces, which were much corroded. The conductor was not in contact with the building, but was kept at a distance of 2½ in. by twenty-one insulators. The earth contact was obtained by bending the tube and burying it in the ground at a depth of from 6 to 18 in., the soil being dry loose rubbish, the earth terminal being only 8 ft. It was placed in a corner formed by a double-stent buttress, which came between the conductor and a lead-covered roof attached to the spire; the distance between the conductor and the lead roofing being about 6 ft. 6 in. The lightning appears to have come down the conductor a certain distance, and finding the road to earth bad, it passed through the buttress, dislodging about two cartloads of stone, and then down the cast iron pipes leading from the lead covered roof, and so to earth.

From the instances quoted, it is evident that it is not sufficient merely that rods of copper should be attached to a building, but it is necessary that once put up, they should be regularly inspected to see if they are in good order, so as to be really efficacious. That this is rarely done is one of the main reasons why accidents by lightning occur in places nominally protected by conductors. It is, perhaps, not too much to assert that at present not one in a thousand of our public buildings in England are regularly tested.

There can be no manner of doubt that in the matter of lightning conductors they manage things better on the other side of the Channel than with us. The French Government are in the constant habit of consulting the most eminent scientific men on the subject of protecting public buildings against the destructive influence of lightning. There is scarcely an instance in which a British Government ever did such a thing. It is true the Houses of Parliament had lightning conductors erected upon them at a very great cost and under scientific advice. But all who understand the subject practically agree in saying that it is very doubtful whether the magnificent pile of buildings in which our legislators assemble is really, that is efficiently, protected. At all events, I understand the earths have never been tested since the conductors were erected in 1852. That the Victoria Tower should have been struck in June, 1868, and slightly damaged, tends to show that the conductors at that time were not in an efficient state.

From the examination I have made I am pretty correct in stating that one-half of our cathedrals and three-fourths of our churches have not even nominal protection. For all that science has done, the Queen may any day be killed in her apartments in Windsor Castle, the Prince of Wales in Marlborough House, and the Prime Minister in Downing Street. To see the difference between England and France in this respect, one has but to cross the Channel between Dover and Calais. At Dover there are huge barracks of great length, on the top of high hills, exposed to the full fury of storms sweeping across the Channel, and the few conductors to be found upon them at long intervals are certainly not numerous enough for efficient protection against lightning, and their efficiency has never, so far as I can learn, been tested. The contrast in this respect on crossing the Channel is the most striking. At Calais the Hotel de Ville, in the Grand Place, literally bristles with lightning conductors, and so all the churches and chief buildings in the town. The same all over France, Germany, and Belgium. Without slavishly imitating our scientific neighbors, we might yet bestow some of the care they do upon the protection of our property as well as of our lives against the terrible effects of the electric force.

ON PROTECTION FROM LIGHTNING.

The condition that determines the direction of an electric current is difference in potential between the two points, the current always being from the point of higher potential to the point of lower potential.

Upon the surface of the earth and within it electricity is constantly being generated by various means: by the friction of the wind upon it, by running water, by heat at the junction of two dissimilar substances, by magnetic disturbances, and so forth. The electricity so generated is quickly distributed to points of lower potential, and the whole is ultimately metamorphosed into that molecular vibration called heat. Let an ordinary magneto-telephone be properly attached to a wire a hundred feet long, and the two ends of the wire be stuck into the earth almost anywhere, and the ear may detect the presence of electric currents by the well known sputtering sounds. These are called earth currents, and sometimes they are very troublesome in telegraphy.

Professor Trowbridge, of Harvard College, found last summer that the ticking of the observatory clock could be detected at the distance of a mile from the line wire that goes to Boston furnishing the time service, and this when the terminals of the experimental line were no further than fifty feet apart. This shows that the observatory battery charges the earth for a great distance every time the circuit is completed by the seconds pendulum.

Suppose now that the positive terminal of a battery or of a dynamo electric machine should be grounded at any place, and the negative terminal at a distant place, say a half mile or more away, the developed electricity would charge the first place to a potential higher than any other neighboring place, and a charged thunder cloud immediately overhead could not discharge itself there so easily as at any other place at a distance, for, as stated at first, it is *difference of potential* that determines the direction of an electric current, and the difference of potential is less in this supposed case than elsewhere. If the potential could be raised as high as that developed in the cloud, it would be absolutely impossible for any discharge to take place between the cloud and the earth at that place, no matter how near they might be together.

Now, the potential of any ordinary battery is relatively weak, but whatever its source may be, it may be raised in various ways: by providing points, by employing secondary coils, by increasing the resistance in the primary circuit. In whatever way it might be done the effect of induction by the cloud would be lessened by it so that the reaction upon the charged cloud would be either to necessitate the discharge at some other place where there was a greater difference in potential, or else to delay it until the potential had been raised still higher, which would only make it still easier to strike elsewhere. The evidence gathered from places where lightning has struck seems to indicate that the conditions which determine the stroke are comparatively trivial. For instance, a comparatively low limb upon a tree may be struck instead of the topmost part, and it is here argued that the charging of the earth at a given place with positive electricity may be a sufficient guard against lightning stroke, while at the negative end of the circuit it would be more likely to strike than elsewhere. This end of the circuit could be so arranged that lightning could harm nothing.

It is also taken for granted that lightning is always positive, and that all appearances of the so-called up stroke are optical delusions. The source of lightning in a thunder cloud appears to be always the same, the so-called latent heat of the watery vapor, the energy of which must be accounted for, and where the precipitation is rapid there is no time for distribution by convection or by conduction.

Perhaps the cost of such a method would render it altogether impracticable for ordinary buildings, but for powder magazines, oil tanks, etc., the cost might not be considered too great.

DESTROYED BY LIGHTNING.

A BOLT STRIKING A MILL IN ST. LOUIS AND EXPLODING INSIDE.

The Walls Rent and the Mill Instantly in Flames—Men Blown Out of Doors and Windows—Several of Them Seriously Hurt.

St. Louis, Aug. 12.—At 7½ o'clock to-night the Atlantic Flouring Mills, at Main and Plum streets, of which George Bain, Esq., is President and Manager, was struck by lightning, and is now a mass of ruins, scarcely a brick or stone of the splendid structure remaining. An explosion seems to have instantly followed the stroke of lightning, and nearly all of the upper part of the mill burst open, and its walls were cracked and riven from top to bottom.

The bolt had scarcely touched the building when fire burst from its every part, and in half an hour the mill and its entire contents were completely destroyed. A number of men at work on different floors were blown through the doorways and windows, receiving serious and perhaps fatal injuries. It is feared that several perished in the flames, but of this nothing is definitely known as yet. The fire spread immediately to the Future City Oil Works, extending on Plum street from Main street to the river front.

The works are now burning with intense fierceness and fury. A warehouse, containing rosin and turpentine, on the same block, is also in flames, and the Plum street depot of the Iron Mountain Railroad, on the opposite side of the street, is in great danger.

Later.—There are about seventy men employed in the mill, all of whom, it is said, are accounted for. Several were very badly burned, however, and were sent to the hospital or taken to their homes. Their names and injuries will probably not be learned to-night.

Wenzel Raizeker, a Bohemian barrel maker, jumped from the second-story window, his clothing all ablaze. He was badly burned on the upper portion of his body, and the skin peeled from his hands. Robert Lorimer jumped from the fourth story and escaped with a broken arm.

Mr. Bain says the loss on the mill will be $140,000; insured for $120,000, mainly in Eastern offices. The future city oil works have been damaged to the extent of about $45,000, the principal damage being to the refinery. The whole establishment is insured for $45,000. The loss on the rosin warehouse is not known.

The stables and storage house for bottles of Anheuser Bros.' Brewing Company, corner of Eighth and Pestalozzi streets, about a mile and a half from the Atlantic Mills, were struck by lightning at the same time and damaged to the amount of about $5,000; fully insured.

ATMOSPHERIC ELECTRICITY.

By David Brooks.

One can scarcely conceive the quantity of electricity that passes from the heavens to the earth through the medium of a thunderstorm, especially so when the storm is one usually designated as severe or violent. One flash or discharge will melt or detach the point of a lightning rod. It does this in an inconceivably short space of time. The quantity of electricity is measured by the effects it produces, and heat is one of those effects. It will produce a certain amount of heat in a certain or measured length of time. A certain quantity of electricity will produce the amount of heat in thirty seconds that half that quantity would produce in a minute. The shorter the time the greater must be the quantity to produce a given effect. The platinum point is melted in an immeasurably short space of time; then immeasurably great is the quantity required to produce this effect. I have spoken of one atmospheric discharge, and must take into consideration the fact that in very violent storms these discharges take place as often as once per second, and have been known to occur in such rapid succession as to enable one to read ordinary printed matter in the night time for minutes without intermission. Reference is made to one thunderstorm, but how many thousands of these storms are there in active progress during every moment of time, when we take into consideration the whole face of the globe? In the same latitude thunderstorms are more frequent on some portions of the earth than others. Travelers in Africa and Asia refer to their great violence and frequency. The Dutch give, as the statistics of the island of Java, that three hundred human beings are killed annually by lightning; and what an insignificant patch upon the earth's surface is the island of Java!

This is one way in which lightning comes from the heavens; but it has been proved that every drop of water falling during a thunderstorm is charged with electricity, and also that there is no want of electricity coming from the heavens at all times in this latitude.

When we contemplate this immense quantity of electricity coming in different ways from the heavens to the earth, we are naturally led to inquire how this electricity is generated. Two theories have been suggested; one that it is produced by the evaporation of water from the earth's surface, and another by the friction of the winds upon the earth's surface. Reasoning from analogy or experiment, very little can be produced by evaporation, because, under that condition, the earth's surface, or that portion of it where evaporation takes place to the greatest extent, is not an insulator, or insulated. When the steam boiler is insulated from the earth, and steam escapes, then electricity is generated; otherwise the quantity of electricity generated is not observable—indeed, scarcely appreciable.

Evaporation is produced to the greatest extent upon the surface of the earth most affected by the rays of the sun, consequently the portion nearer the equator and furthest from the poles. Neither the earth nor the air can be considered insulators, particularly the earth. The air is less an insulator on account of its warm temperature and the amount of moisture it contains. I therefore abandon this theory as producing any considerable amount of electricity.

Now, regarding the friction of the air on the earth's surface, reasoning from analogy, very little can be produced upon that surface of the earth that is not in the nature of an insulator. Whether that surface is the ocean or the land, the surface is a conductor in this latitude, or any latitude where the temperature is above the freezing point. But if we go beyond that point of temperature, toward the poles, then the air and the earth's surface partake of the nature of insulators, the more so as we approach the poles. The ices of the ocean have very little saline matter in them, and water in the form of ice is an insulator in the ordinary sense, and water in the form of snow and ice upon the land is formed simply of rain water, which is still more pure, and still more partakes of the nature of an insulator, with all that the term implies. The insulating properties of rain water, or congealed rain water, double for every ten degrees of Fahrenheit that the temperature is reduced. When we come to consider the very low temperature of the ice in the region of the poles, I have every reason to believe that it is specifically a greater insulator at —50° Fahrenheit than the finest glass in a temperature of 60° Fahrenheit. The same law governs the air in its nature as an insulator; it must be immensely higher in that extremely low temperature than any known substance in ordinary temperature.

With the friction of these two bodies, under these conditions, reasoning from analogy, an immense amount of electricity must be produced.

Therefore, presuming that it is produced at the poles, it would naturally rise and accumulate in the upper stratum of air which becomes a conductor by rarefaction. It is believed that the electricity so produced at or near the poles rises to that region, and then travels or moves toward the equator and returns to the earth in the manner described at the commencement of this article, and when the air, rarefied as before mentioned, is surcharged with electricity, it produces the phenomena of aurora borealis and aurora australis; that the two poles of the earth are immense Holtz machines, generating this almost inconceivable amount of electricity, which we are trying to consider, and that the aurora is simply a visible stream of it from the poles to the equator; that this stream of electricity as it comes to the earth, certainly is positive in its nature, and if there is a current through the higher regions of the heavens from the poles toward the equator, there must necessarily be an equal amount of negative electricity flowing toward the poles on the earth's surface. Now, have we any evidence that such a current of negative electricity is flowing in that direction? We think we have.

We have said toward the equator, but we have no evidence of its flowing or moving in that direction farther south than forty five degrees of north latitude in summer, and perhaps not so far, though it keeps that direction farther south in winter.

The magnetic needle points north and south. It has been supposed to take that position from the fact that the earth itself acts upon it as a magnet. Another theory is, that it is held in position by electric currents passing in a line parallel to the equator.

In either case this force is neutralized by what is known as the astatic needle system; that is, placing in such manner that they swing upon a common center with their poles reversed.

When one needle is magnetized to full saturation, and we commence to magnetize the other until it has sufficient magnetism to move the other needle, the first effect is to give the north pole a direction to westward. We might say that it is held in its position by a force, which we will call ten (10), and that the second needle when magnetized to very nearly that force moves it from its line, say one degree; and as you increase this magnetism to a near approach of equality, it moves still farther until it is equal in magnetic force, and the needles become astatic.

As these forces approach equalization, the tendency is always from north to west;* we say always, but we might qualify it and say during cold weather or during the winter months.

At other seasons of the year there is no regularity in this movement of the pair. We think this is evidence of a negative current passing from the poles toward the equator, and is shown in another way, and that is by taking the constant of the galvanometer when the astatic system points nearly north. In winter it is much easier deflected to the west than to the east. When the aurora borealis prevails, the needles, if nearly astatic, take an east and west direction, and are held very strongly in that position, and have the appearance of a weather vane in a stiff breeze, changing quickly by the least variation in the direction of the breeze, although the current, different from the wind, is flowing in right angles to the direction of the needles. It is a fact that aurora borealis and australis are noted by navigators to be almost always preceded by high winds. In the north they are preceded by winds from the north, and in the south by winds from the south. They are most frequent, also, in cold weather, and when the earth is covered with snow.

In January, 1852, we had deep snow and very cold weather, and probably the most remarkable display of aurora borealis seen for many years in this latitude. The telegraph wires were so charged with electricity as to be almost impossible to work; the wires running east and west were much the most affected. At first this would seem to operate against this theory; but if it is considered that the earth and the rarefied air above are the two conductors of an immense Leyden jar, and the air between these conductors acts the part of the dielectric, these telegraph wires would simply be points approaching the outer conductor, upon which would gather electricity of greater density; and if the currents from north to south simply take the earth or the wires according to the law of least resistance, as ordinary electric currents flow, they would not show themselves upon these wire conductors; but the currents traveling through the heavens and through the earth move like currents through vacuum tubes, at a speed sluggish compared with the speed of currents through metallic or ordinary conductors.

Assuming that atmospheric electricity is generated at the poles, and flows in the lines of longitude toward the equator, these currents must necessarily expand and become of less density. As they leave the polar regions they are expanding in proportion as the lines of longitude diverge, and flow until they come to the belt of the earth on both sides of the equator and embracing each of the temperate zones, and it is in this portion of the earth that these electricities unite again and become neutralized; and one of the visible and demonstrative modes of doing so is through the part played by thunderstorms.

We have to consider the earth and the stratum of rarefied air surrounding the earth as the two conducting plates of an immense Leyden jar, and that portion of the air in contact with the earth and between the two as playing the part of the dielectric. This dielectric, in the neighborhood of the poles, has immense insulating or non-conducting properties, owing to the low temperature and the small amount of moisture it contains. But as it approaches the equator it becomes less an insulator, and is the leaky portion of the dielectric, on account of the greater amount of moisture it contains, as well as its higher temperature.

Now comes the part played by thunderstorms. When the air becomes heated it is lighter from expansion, rises upward, and, becoming cooled by the greater elevation, the moisture condenses into the form of vapor. This body of vapor is of itself a conductor in which the electricity of the upper strata gathers, and when sufficient breaks through the air between the vapor and the earth in disruptive discharges known as lightning. If the vapor extends to a great height the more rapid is the concentration of the electricity, and the cloud simply becomes a point of the outer conductor approaching nearest to the earth, and consequently of the greatest density.

I have compared the two poles of the earth to two immense Holtz machines, generating the electricity of the heavens. Now, the thunder clouds and the earth beneath are the points of discharge where these electricities unite. Very few are aware of the height to which a thunder cloud extends; the lower edge averages about two miles, the upper edge between fifteen and twenty-five. I have measured them often; it is one of the simplest problems in plain trigonometry. There is the lower line of the clouds which is clearly defined, and must be separated from the falling drops between that and the earth.

Now, if a person could be placed at the North Pole, and the earth were cut in two at the equator, and the portion between the observer and the equator removed, and this rarefied circle made visible as a conductor in connection with the thunder clouds, the outer circle, or conductor, would have a serrated appearance, with points converging toward the earth. We have here an exact similitude of an electric machine with the spark passing from the clouds to the earth.

I spent the greater portion of the year 1851 in Mexico, much of the time along the line of the Cordilleras, and have often thought of the part played by mountains that extend into the region of rarefied air. During the rainy season they have storms about these mountains that have every appearance of the ordinary thunderstorm except that there is no lightning—tremendous storm, but no lightning—and the reason I assign for this is that the mountains penetrate the clouds, and the electricities combine by means of the mountains, without disruptive discharge. Almost every day clouds pass over the valley of the City of Mexico, which is itself seven thousand feet above the level of the sea. Atmospheric discharges are much less frequent than in this country, or where the earth is less elevated. Never did I see any atmospheric discharge when the cloud was in contact with the mountain, although the rain from these clouds was heavier for the time being than that of any thunder cloud that I have ever seen. Sometimes the clouds would hang about the mountain and the rain come down in torrents not more than a mile from me, not a drop falling where I happened to be; but the roar of the falling water was almost deafening. I have stood by Niagara Falls, and the roar of the waters there has been far exceeded by the roar of the waters falling from the clouds that skirted the mountains forming the dividing ridge between Puebla and Mexico.

I spent the summer of 1878 in Switzerland without seeing a flash of lightning or hearing a clap of thunder, and I conclude that lightning is certainly much less frequent among high mountain ranges than in comparatively low and level countries.

A thunderstorm is a curious phenomenon. As before stated, the air, after being heated, is expanded, becomes lighter, and rises. When cooled by its great elevation, the moisture is condensed and becomes vapor. It has its similitude in a puff from a steam boiler. When it escapes it is as transparent as the air, but upon cooling it becomes a cloud of vapor; and so does the breath of a whale. This immense animal, warm-blooded, takes in a large volume of air into his lungs, which partakes of the warmth of the body. He rises to the surface and blows it upward, and in cold latitudes it has the appearance of the escape of steam from an engine, on account of the sudden condensation by cooling. The same phenomenon is observable from the breath of a horse in cold weather.

I have spoken of the evidence of negative electricity passing from the poles to the equator by the behavior of a pair of needles; as they become astatic, the north pole tending westward, it is obvious that the needles in latitudes nearer the south pole, under the same conditions, would have a contrary tendency; that is, currents passing from the south pole toward the equator would influence the north poles of those needles toward the east, or should do so to prove this theory correct. The author has never had any opportunity of similar observations in southern latitudes.

If an observer could be placed high above the earth, in a position to view a thunder-cloud, and the electric currents could be made visible to the eye, he would see these currents flowing in all directions toward the thunder-cloud.

Again, if he had in view that belt of earth, the torrid and the two temperate zones, he would find it piled with thunderstorms; and these are simply points where the positive electricity generated at the poles is discharged to the earth.

I have referred to thunderstorms; but there is another phenomenon not coming under that head, known as waterspouts or whirlwinds. It is generally supposed that these gyratory currents are produced by the action of two currents of air flowing side by side in opposite directions. I believe a better explanation is given by the motion of a liquid poured into a funnel. The air when heated breaks through another stratum of air above, and becoming lighter from expansion, rushes upward with great force, and, to use a paradoxical expression, the air gravitates upward in the same manner and with the same gyratory motion as the fluid in the funnel.

Elderly people are familiar with a picture of the maelstrom. My first geography had a picture of a ship being ingulfed and carried down in this whirlpool of waters somewhere off the coast of Norway; this picture represented a ship going down stern foremost, and the sailor had climbed on the bowsprit, trying to economize the last moment of his life. At this date many doubt that the maelstrom ever existed, and think ancient navigators imposed upon our credulity. I am inclined to take a more charitable view of the case, and believe the hole has long since filled up—that is my explanation of the maelstrom.

Intimately connected with this subject is the lightning rod, concerning which I have written before. Franklin announced that atmospheric electricity was identical with frictional electricity. I think he made a mistake—a very slight one, however—in using the word "identical," but should have said it *was* frictional electricity generated at the poles of the earth, as I have endeavored to explain. The idea of the lightning rod is to provide a better conductor than the object we wish to protect, and a harmless path for the fluid from the heavens to the earth.

But at this date it is sometimes most absurdly applied. Five years ago I happened to cross the Atlantic on the steamer Vaderland, an iron vessel with iron masts and iron stays. Some electrical genius had supplied these masts with lightning rods made of about No. 4 copper wire. They ran from the top of the mast down by the side of the ship and terminated in the water. Now, the idea of providing a better conductor for the fluid than the masts of the ship and its iron stays by substituting this copper wire seemed to me rather absurd. I was then on my way to the Vienna Exposition, and this most absurd provision against the effects of lightning often revolved in my mind. No doubt the person who put up those rods had often congratulated himself that he has saved the Vaderland many times from destruction; but I afterwards found that this quintessence of absurdity more than had its parallel. I ascended the dome of the great iron building at Vienna, the largest building of modern times, and I found that equipped from the top to the bottom with a rod of about a quarter of an inch square. This rod was well mounted with barbed points, and carefully insulated in glass thimbles to keep the current from flying from the rod to the building. Now, as the attraction of these metals is in proportion to the bulk or mass, the idea that the lightning should take this rod in preference to the building itself was an absurdity rather more extravagant than that exhibited in the case of the rods on the steamer Vaderland.

A lightning rod, to be effective, should be a better conductor of electricity than the objects it proposes to protect. In most cases it is; but in the case of the steamer Vaderland its attraction, in proportion to that of the ship, was less than one to a million, and the chances of its ever becoming the path of an electric discharge are even more remote. In case the lightning struck the masts of the Vaderland or the Exposition building at Vienna, no harm could follow. But rods are erected upon equally absurd principles to protect oil tanks. These immense iron vessels, containing thousands of barrels of oil, are in great danger of destruction.

Concerning these oil tanks, reference was made in an article of mine on lightning rods, published seven years since by the Franklin Institute, from which I quote as follows:

"Oil tanks are usually well connected to the earth—that is electrically—by pipes running to the distilleries, and for the purposes of filling and discharging these tanks, the connecting pipes being buried in the ground. There have been explosions and fires involving great loss connected with the manufacture and storage of petroleum, supposed to have originated by being struck by lightning. Do the lightning rods we see placed so numerously about these tanks have any effect to prevent these catastrophes? In my opinion, not the least.

"These tanks are immense air-tight vessels, with the upper portion in the form of a dome. The lighter portions of these oils rise to the top of the dome. These lighter and more volatile oils are very inflammable, and when mixed with air are as explosive as gunpowder. The iron tank, being electrically well connected to the earth, is a conductor exercising great attraction for the electricity of the clouds, and should a discharge from the cloud take place, the stroke would center upon that portion of the dome most elevated, and directly upon the plate of iron in contact with the explosive compound. The iron becomes instantly melted or intensely heated, causing an explosion of the vessel, followed, most probably, by a frightful conflagration. This tank, which would, upon first sight, seem to be of a material most safe to protect the contents from fire or accident of this nature, is, upon reflection, exceedingly defective, and in imminent peril during times of thunderstorms.

"An iron rod, fastened to the side or bottom of the tank, and made to extend, say twenty or thirty feet, above the dome, would be a part of the tank as a conductor. The point of the rod would be the point to receive the discharge. " lightning might melt an inch or so of the projecting point of the rod, but would not raise the temperature of any portion of the tank proper, or that in contact with the explosive or inflammable contents. Oil tanks could in this manner be safely protected from the effects of lightning."

At the time this article was published the president of one of the largest oil companies sent the article to the superintendent in the oil regions. The superintendent answered the president that he "had read the article, and he did not by any means agree with its author. He had all his tanks surrounded with rods, and although they had at times been under sheet lightning—the most destructive kind—they had served as a perfect protection."

A little later the company called on one of the insurance offices and recovered $60,000 damages from lightning. Whether the superintendent's views have been modified or not I have not taken the trouble to learn; nor have I been able to learn which he now considers the most destructive, sheet lightning or chain lightning, or some other variety.

In the article before referred to I endeavored to show the great difficulty in making a proper connection of the rod with the earth. To be electrically perfect, it should be of immense size or surface. It is simply the joining of two conductors whose specific conductive capacities differ in immense degree.

To illustrate this, I endeavored to show that to join a copper wire with an iron wire of equal conductive capacity, and seven times as large as the copper wire, as it must necessarily be, the end of the copper wire must be enlarged to the full size, or diameter and section, of the iron wire, in order that the joint should have the full conducting capacity of the copper wire. Now, in making a joint with the earth, the end of the lightning rod must be enlarged in as great proportion as the earth's specific conducting capacity is less.

Dr. Matthiessen gives the ratio of the conducting properties of iron to that with sulphuric acid and water, in the proportion of one of water to eleven of acid—the best conducting liquid known—as 1'0,000 to 1. My own researches would make ordinary spring or river water's conducting proportion to this acid solution at best in the proportion of about 1 to 500.

Now, we will suppose that the rod has a section of one-half square inch, and that it terminates in water. The ground-plate, in order to expose a surface to make the joint of equal conducting capacity to a section of the rod, must be two hundred and seventy feet square, allowing that it conducted from both sides; but, in case it was laid horizontally or parallel to the earth's surface, it must, in order to bring the upper surface of the plate into equal conducting lines with the under surface, be placed sixty feet below the surface of the water. Now, as the earth conducts only in proportion as it contains water, this plate must be enlarged still further to make up for the proportion of earth contained in this water. I will draw upon the imagination of the reader to fill the balance, in order to get the ground-plate to the requisite size and depth to which it would have to be buried.

Nine hundred and ninety-nine out of a thousand of the defects in lightning rods are due to this one thing.

For the last twenty years scarcely a week has passed without a number of patents for improvements in lightning rods. The effect of granting these patents, without a single exception, is pernicious, because they enable the patentee to make the public trust in the rods when they are deficient in the most essential requisite—complete connection with the earth.

Considering the amount expended on lightning rods, and the great source of danger they are instead of protection, it would be a mercy to the community if the Government would take the matter in hand, and appoint a commission to go through the country and take down those that cannot be made effective.

I have been a very attentive observer of the effects of lightning upon buildings in this city for the last thirty years, and have never yet known the occupants injured where gas or water pipes were used. The buildings were often set on fire by the lightning flying from the rods to the gas pipes or from metallic roofs to the gas pipes. A person standing upon a metallic roof would be in great danger from this cause; but if the person be in the first or second story, or in any portion of the building that is below the gas or water pipes, he would be perfectly safe, unless there happened to be a defective lightning rod attached to the building, and this person happened to be between the rod and the pipes at a point where they approached nearest each other.

Gas and water pipes are the best lightning rods ever erected, because they are, electrically, in perfect connection with the earth.

They should extend to the very top of the building, or be connected by a rod running to that elevation. A lightning rod terminating on a railway track is also perfectly safe; but a rod that is not connected with gas or water pipes or a railway track is defective, unless the terminal is of such size and depth as would make it enormously expensive.

And those who do not believe in this assertion are respectfully referred to the amount of property destroyed annually, in the shape of buildings that have lightning rods attached of the latest and most improved patents.

When the discharge is partially obscured from the observer by a cloud, and so far that the report is not audible, it is often called sheet lightning. We can, with equal propriety, call the light, partially obscured by ground glass or by fog, "sheet light."

Heat Lightning.—In the night-time the flashes of lightning can be seen in the sky, apparently coming directly from the earth or horizon. The thunder-cloud, often hundreds of miles distant, is hid entirely from the observer by the convex surface of the earth. The distance to which the light flashes into the heavens is proof that the atmosphere extends much higher than is generally supposed.—*Journal of the Telegraph.*

* Since this was written I learn the effect of the aurora borealis to deflect a needle to the northwest has been noticed by others. Page 448 in a work entitled "The Atmosphere," by Camille Flammarion, of Paris, published by Harper Brothers, New York, 1874, the following statement occurs: "At Spitzbergen, a magnetic needle suspended horizontally by an untwisted piece of silk thread, is turned toward the west; as soon as the aurora begins, the person observing this needle remarks that, instead of being sensibly motionless, it is agitated, passing to and fro from right to left and from left to right."

LIGHTNING RODS ON WAR SHIPS.

37

The Lords Commissioners of the Admiralty direct that in future the captains and commanding officers of Her Majesty's ships and vessels are to be held responsible for ascertaining that the continuity of the lightning conductors on board the ships and vessels under their command is complete, and also for maintaining such lightning conductors in a state of efficiency. In ships which have galvanometers on board the conductors are to be tested periodically, and in ships which are not supplied with such instruments the commanding officer is to apply for the conductors to be tested, when an opportunity offers, at a dockyard.

The Protection of Oil Tanks from Lightning.

CINCINNATI, O., *March 25, 1881.*

To the Editor of the Journal of the Telegraph:

I am glad to notice in the JOURNAL OF THE TELEGRAPH of March 16 the evidence that the subject of protection from lightning is attracting some attention, and hope a free discussion of the subject may lead to a much needed reform in the methods now generally employed. Mr. A. A. Knudson takes exceptions to some points in my article published in the JOURNAL OF THE TELEGRAPH of March 1, which I will reply to, with your permission. In the first place, he takes me to task for not stating how the rods are, or should be, connected to the earth when placed upon oil tanks. I regret my inability to answer the question as to *how they are connected*, but will plead as an excuse for this lack of information that I did not see a rod of any kind upon an oil tank in traveling from Oil City, Pa., to Olean, N. Y., by carriage, notwithstanding I saw several hundred tanks. The lightning-rod is in bad repute in that country, and not very extensively employed.

So much has been said and written upon this subject during the past few years that I hardly thought it necessary to say that the rods should be connected directly to the tanks. If there is an electrician in the country that advocates insulating them and ending them a few feet below the surface of the ground I will agree to discuss the point with him, but I think it a waste of time and space to argue that which everyone concedes. It is true that insulators are used, but it is simply because somebody else used them fifty years ago, and not because there is any scientific reason for it. If there is any good reason or authority for it I have allowed it to escape my notice. My article was based upon the assumption that the rods were useless upon oil tanks, even when constructed upon scientific principles and under the most favorable circumstances. The only point open for discussion in my mind is, *how far above the tanks does the gas ascend in sufficient quantities to be ignitable.* If this limit is determined and it is practicable to extend the rods beyond it, then they will act as a protection, otherwise I think they will not. I have not examined this question personally, but formed my opinion from information obtained from others. Persons who have had large experience in the oil business informed me that the gas ascends a hundred feet or more above the tanks, and upon a bright day it can be seen in the form of a glimmer. If it is true that this gas is heavier than the air, then I see no good reason why rods, when properly constructed, should not be effective. I think, however, that a careful examination will prove that it does ascend, and to considerable heights. If Mr. Knudson desires to know my views as to how the rods should be placed upon tanks to properly protect them, assuming that the gas cannot be ignited at a greater distance from the tanks than it is practicable to extend the rods, then I will be glad to accommodate him by stating that I would select a good quality of iron in the form of a solid rod, about two-thirds of an inch in diameter, and connect it securely to the most elevated point of the tank, taking care to make the conductivity of the joint equal or greater than any other section of the rod, the location and size of the tanks determining the number of rods required. I would not extend the rods to the ground, but simply connect them securely to the tanks. It is well known that discharges of high potential do not follow Ohm's law in regard to conductivity, when the conductivity is ascertained by making measurements with low tension currents, such as is produced by a battery of one hundred and fifty cells. The tendency of high tension discharges is to pass direct to large masses of metal in preference to following a good conductor some distance out of a direct line. If the rods were insulated from the top and sides of the tanks and connected to the conducting pipes at the bottom, there would be danger of sparks passing directly to the tanks at the points where the rods most nearly approached them. The only effect a rod constructed upon the Chambers theory would have would be to bring the sparks close to the tanks where the gas is most easily ignited. I see no reason why the gas cannot be allowed to escape through a burner in such a manner that a discharge would simply ignite it in the same way that a lighted match ignites coal gas when turned on. If sufficient oxygen is prevented from entering the tanks and rendering the conditions favorable for an explosion, then the danger would be avoided.

I would be glad if some one having access to oil tanks would institute a series of experiments, having in view the object of determining the maximum distance from a tank at which the gas is capable of being ignited.

In conclusion, permit me to add, for Mr. Flannery's benefit, that there is no stone or other foundation under the large tanks. The ground is leveled off and the iron laid upon it. Economy seems to be the great object in their construction.

POPULAR SCIENCE MONTHLY.

FEBRUARY, 1881.

ATMOSPHERIC ELECTRICITY.

By Professor H. S. CARHART.

FROM the earliest periods the flash of lightning and the peal of thunder have excited curiosity, stimulated awe, and inspired fear in man; and according to his mythological, religious, or poetic habit of mind has he regarded the latter as the bolt of Jove, the voice of God, or the conscious utterance of the heavens. The explanation of these appearances in the sky is most curious and fantastic, even after the introduction of the modern inductive method. In a "Compendious System of Natural Philosophy," by J. Rowning, M. A., London, 1744, we find the following: "As vapors exhaled from the surface of water are carried up into the atmosphere, in like manner the *effluvia* of solid bodies are continually ascending thither. Now, we find by experiment that there are several inflammable bodies which, being mixed together in due proportion, will kindle into flame by fermentation alone, without the help of any fiery particles. When, therefore, there happens to be a mixture of the effluvia of such bodies floating in the air, they ferment, kindle, and, flashing like gunpowder, occasion those explosions and streams of fire which we call thunder and lightning."

Ever since Franklin identified lightning with the electricity of the frictional machine, an inquiry has been prosecuted into the origin of

STATIC INDUCTION PHENOMENA PRODUCED BY THE RUHMKORFF COIL.

By M. E. BICHAT.

RUHMKORFF's coil is, undoubtedly, the best apparatus to transform dynamic into static electricity: reciprocally this same coil should be the most suitable apparatus for the inverse transformation of static into dynamic electricity. Indeed, if a series of static-electric sparks, produced from a Holtz machine, are made to pass into the fine wire of the coil, currents are induced in the thick wire which excite attention from the extreme facility with which they decompose water and salts. Theoretically one should expect to induce two currents equal in quantity. Now there is nothing of this: it is known that, the experiment being made with the largest induction coils constructed by M. Ruhmkorff, on the one side of the voltameter almost pure hydrogen is always disengaged, and on the other side oxygen. If, instead of water, sulphate of copper is decomposed, at only one of the electrodes is the copper deposited, and the direction in which this decomposition is effected always indicates an inverse induced current. It seems then, according to this experiment, that there is but one current in contradiction with the known facts regarding induction; and it is this apparent contradiction which my researches have sought to dispel.

It was natural first to enquire what might be the influence upon the production of the phenomenon of the cluster of iron wires, which, in Ruhmkorff's coils, contribute in so powerful a manner to the transformation of dynamic into static electricity. I therefore procured a small coil whose soft iron core was not fixed. First the machine was worked without the core, then a bar and a bundle of soft iron wires were successively introduced into it, with the following results:—

When the coil is empty the current is always weak, but perfectly appreciable, and it is inverse when an iron bar is introduced; the deflection of the galvanometer corresponding to the inverse current is much increased if the bar is replaced by the bundle of iron wires.

Besides, it is remarked that the gas disengaged at the voltameter's platinum electrodes is extremely weak and insignificant when the coil is empty, but it becomes quite appreciable on the introduction of the soft iron. In short, the gases disengaged, in the experiment made with the large coil, must be attributed almost totally to the influence of the soft iron.

If care is taken to examine attentively the conditions of the experiment, it will be easy to explain these phenomena so whimsical in appearance. Let us take, first, the experiments on the polarisation of the electrodes, and let us suppose the coil empty. It must be remarked, at the outset, that the current from Holtz's machine is obliged to traverse a very long circuit, of small diameter, of considerable resistance. The positive and negative electricities accumulate little by little on the balls of the exciter until the strength being sufficient the spark bursts forth.

We may more simply express this fact by saying that the spark commences slowly and finishes abruptly. There result two induced currents equal in quantity, but of very unequal potential. The potential of the direct current, which corresponds to the break of the primary current, is enormously opposite to that of the inverse current proceeding from the slow establishment of the spark which constitutes the inducing current. The inverse current decomposes the water in the voltameter slowly, and deposits on the platinum a very large quantity of microscopic gaseous bubbles, that are not disengaged, and consequently create polarising currents.

The direct current which afterwards arrives decomposes the water, but, as it lasts a very short time, the result is that this decomposition is effected very rapidly. The gas bubbles are larger, are disengaged immediately from the platinum, and, producing only a very feeble polarisation, are unable to destroy the polarisation of the inverse current.

The apparent production of a single inverse current is due, then, to the difference of potential of the two induced currents; and, hence, we ought to expect to see the galvanometer's deflection lessen if—by any means whatsoever—we can lessen the potential of the direct current: this may be done with the help of diaphragms. If we introduce into the empty coil a tube of continuous copper the galvanometer's deflection immediately decreases. It remains, on the contrary, the same as it was before if we replace the continuous tube with a slit one.

Let, now, a bar of soft iron be introduced into the coil. The phenomena produced will be the same as when the coil was empty; but at the same time the magnetisation of the soft iron will give rise to other induced currents in addition to the first. To comprehend thoroughly what takes place we must remember that of the two currents, direct and inverse, it is the direct which magnetises the strongest, because it has the highest potential. We may, then, say that the magnetisation produced by the first spark is direct. On the other hand, we know that a certain time is always necessary to demagnetise a piece of soft iron. It follows that the sparks of Holtz's machine, succeeding one another with rapidity, the magnetisation produced by the first will not be completely destroyed on the arrival of the next. This second spark adds its effect to that of the first, and augments the magnetisation of the soft iron.

The considerable augmentation of the effects produced by the inverse current when we replace the bar with a bundle of soft iron wires easily explains itself, if, in the phenomena of static induction, as well as in those of ordinary induction, the interposition of diaphragms lowers the potential. The demonstration of this fact I trust I have clearly shown.

To recapitulate:—If an intermitting battery current be made to pass into the thick wire of a Ruhmkorff coil, two currents of contrary directions are induced in the fine wire, and, for a certain explosible distance, there appears to be only one single current produced. This current is *direct*, and the sparks produced therefrom have in all respects the semblance to sparks from static electricity. Reciprocally, if into the fine wire of the coil a series of sparks from static electricity be made to pass, we induce, in the thick wire, currents in all points analogous to those furnished by the battery; and in studying these currents by means of a voltameter there seems to be only one current which is *inverse*.

8

INDUCED CURRENTS AND DERIVED CIRCUITS.

By SAMUEL E. PHILLIPS, Jun.

In the "Journal of the Society of Telegraph Engineers" I have recently noticed an article with the above heading, extracted from "Silliman's American Journal," in which the writer, Mr. John Trowbridge, seems under the impression that the

in any two cases. The electromotive force being constant, and the internal resistance of the electromotor (whether battery or coil) being so small that it may be disregarded, then it is easy to see that with any shunt we shall in all cases obtain about the same deflection on the galvanometer, a constant deflection in the case of a battery, or an impulse of constant force when dealing with an induced current. The laws of derived circuits apply with equal exactness in each case: this we can clearly show by Mr. Trowbridge's own figures, although he draws a contrary inference from them. He says—"A reflecting galvanometer of large resistance was included in the secondary circuit, and connected by copper wires of very small resistance with the coil in which the secondary currents are produced: *the resistance of these wires was infinitesimal in comparison with the resistance of the galvanometer.*" This is somewhat vague, for it would lead one to suppose that it was only the leading wires which had an infinitesimal resistance in comparison with the galvanometer, and that he had omitted to mention the resistance of the secondary circuit in which the induced current was produced; and one might naturally picture the secondary circuit of an induction coil as the source of current, in which case there would ordinarily be a considerable resistance involved; but a glance at the figures show that this was not the case, and that the infinitesimally small resistance included both the leading wires and the coil under induction; and a little later this is further indicated, for the writer says—"With an inappreciable resistance outside the galvanometer coils, the shunts made no difference in the deflection of the galvanometer needle when the shunts were not less than 3 ohms; below this the current divided"!—the last five words conveying the idea that previously no division had taken place, which is later on contradicted, in instancing one galvanometer shunted by another galvanometer of the same resistance, the same deflection being obtained on each, when joined as a parallel circuit, as upon one alone. How Mr. Trowbridge could have come to this last result, and not have seen the true bearing of the case, it is hard to understand. With his galvanometer of 5880 units resistance he obtains a deflection of 210 divisions, the resistance external to the galvanometer practically equalling 0. And we may express it thus, E being the electromotive force of the induced current—

$$\frac{E}{5880} = 210 \text{ divisions.}$$

On shunting the galvanometer with an equal resistance we have—

$$\frac{E}{\frac{5880 \times 5880}{5880+5880}} = \frac{E}{2940} = 420 \text{ divisions;}$$

or, having halved the total resistance in circuit, we get a current of double quantity, which, having two equal channels to flow through, divides into two halves; 210 going through the galvanometer, as in the first case when no shunt was employed, and 210 by the shunt; whereas Mr. Trowbridge would seem to infer that, had the law of divided circuits been correct, we should have obtained only 105 divisions, which would have been quite true if we had been simply dealing with a given amount of current in the several cases. We therefore see that

On the Penetration of Charges in Insulating Bodies, Fixed and in Motion. By M. Righi.

With certain precautions (specified) it may be shown that an insulating plate, charged by friction on one of its faces, acquires on the other a charge of the contrary sign when the latter touches a conductor, especially an uninsulated one, or when it is touched by the hot gases of a flame or of burning charcoal, or by moist air, or is near a conductor armed with points. In the case of moist air, the induced charge forms spontaneously by degrees. Its limiting value in every case is such that its action on the conductor (or on the neighbouring points of the gas) destroys the opposite action of the rubbed face. If between a rectangular ebonite plate A, charged negatively, and an uninsulated metallic comb parallel to the two small sides of the rectangle, there is a second plate B of the same size and parallel to A, B acquires a positive charge, certainly less in absolute quantity than that of the inductor; but as it occupies a small surface on B, its superficial density may be greater. If the plate B be then moved so as to glide all over the comb, it may acquire a positive charge greater than the negative of the plate A. If the two plates be enclosed together in an insulated conductor, this will appear positive. The induced charge of density greater than the inductor may also form on one or the other of the two faces of the rubbed plate itself. It is sufficient to rub strongly a rectangular plate, and then to make it glide over the comb, to find it afterwards showing the contrary sign. Thus, if between the rubbers and the combs of a friction machine, a comb communicating with the ground be brought near the glass plate, the glass which comes positive goes away negative and the conductors of the machines are charged negatively. These and other experiments described throw light on many phenomena of induction-machines.

Tel Journ Oct 15 76

Professor Melsens, of Brussels, recently constructed a rhe-electrometer on the principle of that of Marianini. It consists of a compass with a coil of wire under it wound on a hollow ebonite cylinder, whose axis is at right angles to the magnetic meridian. One end of the coil communicates with a line of telegraph wire, the other with the ground. A piece of annealed steel wire without polarity is placed in the helix. Immediately the helix receives a current the bar becomes a magnet, and deflects the compass west or east, permanently. A new wire can be substituted for fresh observations. M. Melsens suggested in the Belgian Academy that a system of observations by this means, at a large number of telegraph stations, might throw much light on the electric phenomena above us in the clouds, in our houses, and under our feet in the ground. The hint was acted upon by the Belgian telegraph authorities, and observations are now transmitted regularly from various offices to the central administration. As to the nature of the electrical effects, M. Melsens states that in one observation, during a thunderstorm at Bruges, between 3.48 p.m. and 7.55 p.m., the wire not being changed, the needle passed ten or twelve times from east to west, indicating discharges violent enough to reverse the poles of the wire.

Tel Jnl Feb. 15. 78

A SIMPLE ELECTROSCOPE.

M. Rameaux lately brought before the Société des Sciences of Nancy a very simple and sensitive electroscope. It consists of a fine fibre of white silk, fixed at one end by means of a little wax to any support, and free to oscillate in any direction under its point of attachment.

A single thread would, of course, suffice for the ordinary purposes of electroscopy properly so called, but it is preferable to employ two near each other, taking care to space them so that they cannot foul each other during their swing, or influence each other reciprocally.

One of the threads is charged to strong repulsions by means of a glass rod charged with positive electricity; the other is charged in a similar manner with a stick of resin charged with negative electricity. Every body which attracts one of the threads so charged, and repels the other, is necessarily electrified. Its electricity is of the same sign as that of the thread which it repels.

The sensibility of these electroscopes is greater, within certain limits, as the threads are made finer, longer, and less conducting.

If the finest sewing silk of commerce be untwisted, each of the parts or strands obtained will make an excellent electroscopic pendulum, which, if about sixty centimetres long, is very handy, and suffices for almost all tests. White silk is preferable to coloured.

The motions of these threads, if well charged, are very considerable, even when the bodies presented to them contain but slight charges of electricity. When the threads are not excessively fine, disturbances of the air do not destroy the observations so much as might be supposed. In the first place, these disturbances can be almost entirely removed; and, furthermore, the threads, even when agitated, obey so well any electric attractions and repulsions that it is absolutely impossible to mistake or detract from their evidence.

M. Rameaux has found this arrangement in all cases more sensitive and sure than a carefully-constructed gold-leaf electroscope, which he used for comparison.

This system also recommends itself in several ways, for instance:

1. It is so simple that every one can construct and use it.
2. It costs nothing; no special support being necessary. The threads can be fixed to any projecting piece, as the edge of a table; the only condition being that they may hang freely.
3. It can be set up in a moment, and consequently is at once ready for any unexpected requirement; whereas a gold-leaf electroscope long unused requires to be dried for hours.
4. It works perfectly, whatever the hygrometric state of the atmosphere.
5. It can be employed to show electric phenomena to a numerous auditory. With long, thin fibres and highly electrified bodies, the experiments are very telling.—*Bulletin de l'Association Scientifique de France.*

9

denser, we interpose a layer of alcohol between the mercury and the platinum point. The roaring ceases when we suppress the alcohol, and leaves only a layer of air, also, when the point is dipped into the mercury. These facts indicate that the current, in the first case, passes across the glass, across the alcohol in the second, and that its *passage is intermittent.* The tube of iron submitted to a rapid succession of magnetisations and demagnetisations occasions the feeble roaring sound heard in the coil. A galvanometer indicates only a continuous current, as would be expected when the intermittence is so rapid. I think the cause of the intermittence to be the condensing action of the glass and the alcohol. When the two faces of the insulating substance have acquired a certain electric potential, a discharge takes place across the insulating layer; the magnetism of the core increases during the charge, and decreases during the discharge. The sound is produced during the diminution of the magnetism. Another experiment:—The platinum point is mounted in a fixed hammer. The mercury and point communicate respectively with the armatures of a condenser of 1 square metre surface. The rest of the circuit is arranged as before. The point being plunged into the mercury, it is gradually raised until the spark just crosses the alcohol. There the point remains fixed, a succession of sparks is established, and continues for some time. The mercury evidently oscillates beneath the point. The possible cause of this oscillation is that the spark is formed by the vapour of mercury. The elastic force of this vapour depresses the level of the liquid. This purely mechanical cause may not be the sole one. The facts would appear to show that *the interposition of a sufficient resistance in a voltaic circuit determines the intermittence of the current.* The laws of this intermittence must be studied with the condenser, in order that the periods may be sufficiently long for observation. We should not neglect to draw the possible inference that a *current is a succession of changes which are accomplished periodically in the circuit.*

Poggendorff's Annalen der Physik und Chemie. No. 7. *Reaction of Secondary Currents in an Unchanged Circuit on the Primary Current of a Leyden Battery.*—By M. Riess.—The secondary current has a weakening action on the primary. The reaction of a series of secondary currents decreasing in strength because of the conveying wire being changed, undergoes two phases. In the first (commencing with perfect conduction of secondary current without sensible weakening of the primary), the action increases, and so the primary currents decrease in strength; in the second, the reaction decreases, hence the primary currents become stronger. If we take two secondary currents in the first phase, the weaker corresponds to a weaker primary; if in the second, to a stronger. The latter effect is not remarkable, and the former may perhaps be explained by the weaker secondary having a longer duration, and so obtaining a firmer hold (so to speak) on the primary. For long, there was no other known way of altering the secondary current produced in a secondary wire at given distance from a given portion of the primary than that of altering the wire which closed the secondary circuit. The experiments were made with different secondary wires. Other methods are now known. Thus, suppose, besides the secondary circuit, a second (auxiliary) wire, whose ends may be either connected or free. When they are connected, the secondary current is stronger than when they are free. Greater changes of the secondary current may thus be obtained if the wire used for closing the secondary circuit is not drawn out, but bent in the form of a narrow N. The best way, however, is to arrange the wire spirally (the auxiliary wire having this form also). M. Riess experimented with the arrangement

Researches on Electric Condensation.—By M. V. Neyreneuf.—Under several circumstances of its use, a condenser formed of a plate of glass is a true electrophorus, giving from its two faces, positive or negative, electricity or both at the same time. We may explain all the ordinary phenomena of condensation by attributing to the insulating plate an exclusive *rôle* in their production. Only one difficulty presents itself—that of the occurrence of free electricity on one of the plates; but it is to be remarked—(1) That this electricity is inconsiderable in quantity; (2) That we can without sensible modification impart, by means of a Holtz machine, free electricity to the two plates at once. The study of the electrophorus is, therefore, the study of the condenser.

Length of Spark.

The spark given by my electrical machine is generally about 6in. in length. A few days ago, however, I contrived to get two additional inches simply by attaching to the ~~P. C.~~ a terminating ball somewhat larger than the one usually employed. I mention this merely as affording an occasion for suggesting to those amateurs of "ours," who are disappointed with the results given by their electric machines, as estimated by the length of spark, the propriety of so varying the spark-taking portion of their apparatus as to give their machines a fair chance of doing their utmost.

Tel Jour Sept 1. 1873

On Electrical Condensation.—By M. Neyreneuf.—Air surrounding an electrified body suffers, like all other insulating bodies, the effect of penetration for the nearest molecules, and of orientation for those the most distant. The first would act, in the production of a spark, not by direct transmission, but like the isolating plate of a condenser, that is to say, by decomposition, by induction. This generalisation of the mode of action of an insulating medium cannot be proved by means of a condenser with a stratum of air, but we can justify it by remarking that a conducting ball, on an insulating stand, electrified, and then discharged by intimate contact with earth, preserves, during a very short time, an electrisation of the same kind, very sensible to the electroscope. By varying the conditions of the experiment, we see without difficulty that the residue observed is not due to the insulating substance forming the support. The fluid which has penetrated a certain thickness of air cannot be instantaneously neutralised, towards the exterior layers, which are at that time able to manifest a repulsion of the gold leaves. If we consider a Ramsden machine, in communication with an ordinary condenser, one derivation is established by the air and one by the condenser. The relative intensity of the two derivations varies with circumstances the most insignificant in appearance, and the charge of the insulating stratum is only constant (to produce a spark at a constant distance) under exceptional conditions of regularity in delivery from the machine. We can much reduce the influence of the derivation by the air, in using a Holtz machine, if we place it in communication with a strong battery. Under these conditions, the charge of the insulating plate soon produces, by an effect analogous to that of the secondary currents of batteries, the discharge of the machine and its charge in an inverse direction. We can assimilate the phenomenon of condensation to a true polarisation of the electrodes, and further this assimilation by means of the charge by cascade. Two condensers placed in cascade easily cause the interversions of charge which one alone was unable to produce. If we place a universal discharger between a Ramsden machine and some condensers in cascade, we prove that the number of sparks which we can cause to spring between the buttons of the discharger is limited, and that this number is as much smaller as the number of the condensers is greater, as if the tension of the secondary current increased with the number of elements. The derivation by the air then goes on increasing, and a Henley pendulum indicates, under these conditions, greater or less divergences. The charge of an insulating stratum varies with the nature of the electricity of the charge. This law, established by Matteuci in the case of feeble quantities, is easily verified for strong charges. The time of a charge, which permits, as we have seen, the penetration of the fluids into layers deeper and deeper, permits also, by lateral conductibility, the propagation of the fluids on the very edges of the insulating stratum. When these edges are sufficiently charged, their effect is added to that of the stratum itself in such a manner that some very irregular perturbations are produced in measures by the electroscope.

Proceedings of Societies.

THE SOCIETY OF TELEGRAPH ENGINEERS.

The Meetings of this Society were resumed at the Hall of the Institute of Civil Engineers, Westminster, on Wednesday evening, the 12th inst.

The chair was taken by Mr. Cromwell Varley.

A paper "*On the Quadrant Electrometer*,"* by Mr. John Munro, was read by the secretary. The paper opened by stating that without proper means of measurement no science can prosper and become applied. As every electric phenomenon is primarily due to differences of electric potentials established among matter, an electrometer, or instrument for measuring differences of potentials, is a primary necessary to the advance of our knowledge of electricity, and our application of it to the arts. Since the last century various rudimentary electrometers have been contrived for experimental purposes, but these have been more or less crude and imperfect. The modern electrometer, besides answering the uses of scientific research, should be fitted for the commoner work, and should be adapted to measure alike the agency of a thunder-storm and the variations in the electromotive force of the most constant galvanic element. Its range and sensibility should therefore be great. The quadrant electrometer fulfils all these requirements to a hitherto unequalled extent, and for station employment far exceeds all others in utility. Difference of electric potential or electromotive force is thus defined by Sir William Thomson:—"The amount of work required to move a unit of electricity, against electric repulsion, from any one position to any other position, is equal to the excess of the electric potential with the second position above the electric potential with the first." Thus the difference of electric potential takes the form of mechanical work. The quadrant electrometer is, like all other highly-perfected contrivances, an instance of that process of evolution which goes on among mechanical as well as natural creations. Though so complete and complex in its present form, it had for its progenitor a large iron tank and a three-legged stool, but since that early day it has gone through several improving modifications. The paper proceeded to describe at length the various details of the instrument, and the method of using and adjusting it. These descriptions were illustrated by diagrams, and without such adjuncts would be quite unintelligible. Perhaps the best method hitherto tried of testing submarine cables by the electrometer has been successfully employed by Sir Wm. Thomson and Mr. Fleeming Jenkin in connection with the Great Western Telegraph Company's cables and the Brazilian Cable. This was fully described by Mr. Jenkin in a paper read to this Society on the 26th March. The use of the quadrant electrometer in research gives results of absolute measure. "The first step," says Sir William Thomson, "towards accurate electrometry in every case is to induce, from the scale-readings, numbers which shall be in simple proportion to the difference of the potentials to be determined. The next and last step is to assign the corresponding values in absolute electrostatic measure." These steps can be accomplished by means of this electrometer. Force is measured in grammes weight. The quadrant electrometer has also been long used as a self-recording measurer of atmospheric electricity. Its applications, however, are extensive in the whole range of electric science. In the meteorology of the future it seems destined to play an important part, and doubtless its aid will be invoked in other branches of human knowledge. Its importance as an instrument of electric research, and as an appliance of the telegraph engineer, is rapidly becoming recognised throughout Europe and America.

Mr. W. H. Preece said that he had listened with a great deal of interest to the paper just read. It was very difficult to follow from an oral description the details and architecture of an instrument such as the quadrant electrometer, and especially so when, unfortunately, the instrument itself was absent, although had they had the instrument before them they might not have been much more enlightened, for it was one which required very careful examination in all its parts. It was destined to become a most valuable auxiliary to the electrician, and he questioned very much whether any electrician's or telegraph engineer's apparatus could be complete until he possessed one of these appliances. Certainly no laboratory could be called a laboratory until one was on its shelves. The principles upon which the quadrant electrometer are constructed were, like the principles of all really beautiful instruments, excessively simple, and indications were given by a simple solution of one of the earliest problems taught in all education, the simple parallelogram of forces. The indicator or needle moving in the electric field was actuated in two directions, and it took up the resultant position; and by that means we had depicted upon a scale a spot of light which could be registered with the greatest ease, and which gave an absolute indication of the forces present. The instrument, as had well been remarked in the paper, was an example of that principle which was now gaining so much ground in philosophy in general—the principle of evolution. It was also an excellent example of Darwin's theory of natural selection and the survival of the fittest. All those who had experimented had, at different times, made use of electrometers and electroscopes of various kinds. The old gold leaf, and, in *fact*, the old straw, had gradually by this principle of natural selection been created into the quadrant electrometer. He did not think that any museum or any school could be complete until it had a kind of historical series of instruments showing the gradual change by which one form had passed into another. Speaking from experience he could say that young hands were far more easily taught to value *all* the alterations and details of an instrument by being shown the different stages through which it had passed in its career. Hence this society, when it became rich and possessed a museum, as he hoped it would, could not possibly do better than have a series of electrometers giving examples of this principle of evolution by showing all the stages through which the instrument had passed. There was one part of the instrument which was rather cursorily passed over in the description, but which really was one of its most beautiful points; that was the *replenisher*—the simple and easy means by which we were able every moment to keep the instrument up to its proper standard, and by which we were able at all times to obtain comparative and actual results. This replenisher was one of those many inventions of Mr. C. F. Varley. That gentleman being present, he would no doubt explain the replenisher in his usual clear way. The principle of accumulation upon which it was based was fully explained by him in the year 1860. That principle should be understood by everybody, because this was not the only instrument which was based upon it. Holtz's and other machines were based upon the same principle. The uses to which the quadrant electrometer had been put were mentioned in the paper. It had been for some time in use in Hooper's works. Its great merit was that, in testing with this machine, the experimenters could watch with the eye exactly what was going on. It was not as if they used a galvanometer, and had to dodge the cable to get the proper indications. When this electrometer was applied, the

The axis has upon it a pulley which receives a driving cord from a wheel which is rotated by hand; A¹, A¹, are tinfoil strips fixed upon the face of the disc, and A², A², are studs in metallic connection with the strips A¹; C, C are metallic collecting combs, and D, D, are the inductors; both are carried upon insulating

Mr. Varley proposes to employ his electrostatic multiplier in connection with the electric light, so as to render the latter constant. For this purpose, he places its conductors near the carbon holders, so that a stream of sparks may pass to them constantly so long as the light is being maintained. The high tension electricity, which in this manner is caused to pass between the carbon points, effectually maintains the magneto-electric discharge.

Students' Column.

Electrification of Dielectrics.

When a battery is connected with the conductor of an insulated cable, the current which flows into it is observed to decrease from the first moment of contact, until finally, after an hour or so, it arrives at an apparently constant value.

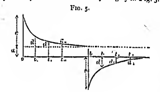
The attention of Mr. Willoughby Smith was first called to this fact during the manufacture of the (1858) Atlantic Cable. Subsequently (1859), quantitative measurements of the apparent increase of resistance due to this so-called electrification, were made at Mr. R. S. Newall's manufactory, at Gateshead, by Mr. Fleeming Jenkin.

The first rush of electricity into a cable core is due to three causes:—

(1). The electrostatic charge;
(2). Electrification or absorption; and,
(3). Leakage through the insulator.

The electrostatic charge lasts only an instant, and its amount depends, other things being equal, upon the ratio between the thickness of the conductor and of the insulator. The electrification, or absorption, at first great, diminishes rapidly, and ceases apparently altogether after some hours. The leakage, however, is constant. In comparing the relative values of these three sources of currents by means of a galvanometer, it is necessary to connect its poles by a shunt in reading the charge, after which the shunt may be removed, and the diminishing deflection due to electrification and leakage observed. After some hours, the electrification being complete, the deflection becomes permanent, and we get the true conductivity of the insulator. If we now remove the battery, and allow the electricity which is within the cable to pass out, through the galvanometer to earth, we get a very high deflection at first on the other side, and this gradually diminishes to zero. The curve obtained by this experiment is shown very roughly in Fig. 5.*

FIG. 5.



The ordinates represent the observed currents, the abscissæ the times after contact. At the point, O, the battery being connected to the cable gives the deflection $(a+e)$, due to all three causes—charge, electrification, and leakage—combined. Further on, after an interval, t, the deflection $(d+a)$ is due to electrification and leakage. After t_1, it would be a, due only to leakage. After an interval, b, the battery is removed, and the needle is deflected to the negative side. At the first instant it is $-e$; after an interval, t, from the removal of the battery it is $-d$; and after t', it is $-d'$. Thus we find that (independently of the leakage) the electrification and dis-electrification of a cable go on at the [...]tion as far as is practicable.

55	21,200	2,770	—
60	21,800	2,790	509

The rate at which electrification takes place depends upon the temperature of the cable.—When gutta-percha is cold, its apparent resistance increases in a higher degree after the application of the battery than when it is warm. It would appear from this that the softer the gutta-percha the less it is capable of absorbing electricity, and probably it might be warmed up to a point at which it would show no electrification whatever. This is evident by reference to the above table of measurements of a knot of French Atlantic (1869) core; when at 0° C., its resistance, as appears by column 2, was—

After 1 minute = (7,540) = 100
" 10 minutes = (14,400) = 191
" 1 hour = (21,800) = 289

The same coil heated to 12° C., and re-measured, gave the following resistance:—

After 1 minute = (1,666) = 100
" 10 minutes = (2,275) = 137
" 1 hour = (2,790) = 167

Showing a considerably lower rate of electrification. But this is still more observable at 24° C. (column 4), at which the same coil had a resistance—

After 1 minute = (369) = 100
" 10 minutes = (472) = 128
" 1 hour = (509) = 138

It appears from this that the resistance of gutta-percha, when at a temperature of freezing water, increases in resistance between the one minute and one hour 189 per cent, whereas at 12° C., its resistance increases, in the same time, only 67 per cent: and when heated to 24° C., increases only 38 per cent.

ON STATICAL ELECTRICITY AND SUPERFICIAL TENSION OF LIQUIDS.

In a memoir recently published, M. Van der Mensbrugghe inquires if statical electricity produces, like heat, variations in the contractile force of liquids. In the first part he gives a *resumé* of researches, preceding his own, which have treated of the relation of static electricity, if not to superficial tension, at least to the cohesion of liquids, which is intimately connected with the contractile force. He finds only two conclusions distinctly enunciated; the first by Erman and by M. Brunner, according to which static electricity exerts no action on the cohesion of a liquid; the second, affirmed by M. Plateau, that capillary forces do not undergo sensible diminution under the influence of electricity. From this it should follow that the tension of a good conducting liquid remains the same whether the liquid be electrified or not; and this is the conclusion to which the author is led by his experiments (described in the second part of the memoir), of which the following are the most important:—

A bubble of glycerine liquid, 6 to 8 centimetres in diameter, is deposited on an iron ring about 2 centimetres radius, supported on three feet, and placed below and at about 20 centimetres distance from the conductor of an electric machine. When the latter is electrified, one observes the effects that have been described by M. Cauderay in the case of soap bubbles; the liquid sheet elongates in the vertical direction, the curvature increases at the upper part, and decreases towards the base; and the more so as the charge becomes stronger. It is evident that then the quantity of electricity developed is greater at the summit than near the base of the film; consequently, if the electric fluid has an effect on the superficial tension, it is at the summit that the variation of this force will be most pronounced. Now, one does not observe in the film, either rapid descent of the liquid or attraction of the lower parts of the bubble towards the top; the colours appear in their usual way, even when a very strong charge is given to the conductor. The effects, then, are just as if the bubbles were forced mechanically to take the form described; and this would not alter their tension.

In order to see if the electric fluid would modify the contractile force of a full liquid mass, the author procured a U-tube of glass, the two branches of which were 12 centimetres in length; the internal diameter of the one was 10 m.m., that of the other only 1 m.m. Having dried the tube carefully, and well moistened the internal walls, he poured in a quantity of distilled water. In the narrow branch the column of water rose to about 27 m.m. above the level of the water in the wide branch. By electrification of the liquid in the latter, he did not produce, apparently, the least displacement of the column, even with very intense electric charges; whence he inferred that the electricity did not cause the tension of the liquid to vary.

If, instead of using a liquid of imperfect conductivity, the experiment be made with mercury, the effect is the same, there is no change through electrification.

Rigorously (M. Van der Mensbrugghe says) these facts might not appear conclusive; for if we electrify the water about the capillary tube, the tension, and consequently the molecular pressure due to the superficial layer of distilled water, might be altered without the capillary column diminishing in height. This was the result of the following experiment by M. Duclaux:—A thin layer of alcohol or oil is poured on the water surrounding a capillary tube, and no change is observed in the height of the column raised. To refute this objection M. Mensbrugghe first endeavours to show that M. Duclaux's experiment may be easily explained by means of Laplace's theory properly interpreted; then that in the case of electrification of water, the conclusion previously stated is the most legitimate one.

He thought it interesting to ascertain if static electricity would influence the equilibrium of a liquid column suspended in a tube, the internal diameter of which was near the maximum limiting value determined by M. Duclaux. This physicist repeated before him one of his experiments with a tube 19·14 m.m. internal diameter; it chanced that the stability of the column was very weak, notwithstanding the difference in value between his diameter and the maximum value realisable, 19·85 m.m. The tube was closed at its upper end by a cork covered with gum-lac; this cork was traversed by a copper rod terminating without in a small ball, and prolonged into the interior of the tube to about 7 m.m. of the open section; the whole of the apparatus serving as support was insulated.

Immediately the liquid column was suspended, the author removed all neighbouring conductors which might have a disturbing action, and then connected the copper rod with the conductor of the electric machine. Notwithstanding the electrification, the weak stability of the column was perfectly preserved; but if any good conductor was brought near the terminal liquid layer, this was sufficient to make the water flow at once.

En resumé, it follows from my experiments that the superficial tension, either of a film, or of a full mass, of good conducting liquid, is not modified by static electricity.

But this conclusion includes implicitly another consequence which seems to me important. It is that static electricity, instead of being expanded in the interior of the extreme layer of good conducting bodies, is found, on the contrary, entirely exterior, and simply applied against the limiting surface of these bodies. Indeed, if, as is commonly believed, the electricity had its seat in the interior of the superficial layer of a good conducting liquid, how are we to suppose that the repulsive forces acting between the same molecules charged with the same electricity would not diminish the tension of the superficial layer? seeing it has been proved that this tension is modified by the slightest causes, such as a very small elevation of temperature. Besides, the mathematical theory of electrostatics leads us to conceive of electric layers distributed in conductors, as being exterior to the surface of these, but immediately applied to them.

Les Mondes. Vol. xxxvii., No. 14. August 5, 1875.

On a Transformation of the Electric Spark from Holtz's Machine.—M. Demoyet.—It is well known that the sparks obtained from a Holtz machine are compounded of several continuous streams of luminous filets, of a brilliant white colour. In reality the luminous jets succeed each other, as may be verified by rapidly changing one of the poles, and it is merely the persistence of the retina's image which gives the appearance of several simultaneous jets. Now, let one of the poles of a Holtz machine, or of a coil, be put in connection with a Rohmkorff insulated metallic circle, in whose interior turns a bent wire terminated by a point or a ball, and joined to the other pole. This wire in turning changes its position parallelly to the metallic circle, the sparks are given out successively, and, if the movement be regular, at equal distances: the effects may be varied by enlarging or contracting the circle, or lengthening and shortening the movable stem. If a resistance be interposed between the two points, by means of an isolating plate pierced with a small hole, the sparks become intermittent, and are accompanied by a reddish nimbus. If a resistance coil of fine wire, two- or three-tenths of a millimetre thick and 50 to 100 metres long, wound on an insulated core, be placed in the circuit (and plunged into petroleum to increase the helix's insulation), intermitting sparks are obtained with a reddish nimbus, in all respects similar to those from the Ruhmkorff coil, and having the same properties. If, instead of winding the wire of the resistance coil upon itself, it be stretched in a straight line, to avoid extra currents, analogous—but less intense—effects to the foregoing are obtained. From this we may conclude that this transformation of the spark is due—(1) to the resistance of the wire; (2) to the induction of the current upon itself. When a soft iron core is used for the coil the results are decreased, on account of magnetisation; and this explains why the results obtained from the fine wire of a Ruhmkorff coil are less than those from a fine wire simply twined around an insulated core. A portion of the electromotive force is employed in producing—(1) a current in the thick wire; (2) magnetisation in the soft iron core.

ON INDUCTION CURRENTS PRODUCED IN TELEGRAPH WIRES.

By M. LAGARDE.
Inspector of Telegraph Lines.

For a very long time induction phenomena have been known to physicists who have, however, only studied them in their laboratories. The difference between their circuits and those of telegraph lines is so great that it is only of late years it has been convincingly ascertained that a current sent on one aërial wire will induce a current in the other when they are near each other for a sufficient extent. Morse, and other machines of that class, were unaffected by these induced charges, hence the belief in their non-existence on telegraph conductors. When, however, Hughes's apparatus came into use, it was noticed in some places that it was not always possible to work at the same time through two neighbouring wires with his apparatus, whilst no obstruction was offered to the use of the Morse on the very same lines. For a long time it was thought this was owing to leakages between the two wires; but it is now recognised that induction is the sole cause. I have undertaken, since 1869, numerous experiments on this subject, and though the results are incomplete, and shew scarcely more than the truth of the fact without indicating its law, I put them forth to the world in the hope of completing theoretic conclusions when other facts shall be revealed to me by future experiments. When a derivation exists between two lines, and when a current is sent on one of them, if on the other there is a polarised electro-magnet receiver—such as Hughes—it will work if the derived current is strong enough, and if it is of a suitable direction in the coils of the electro-magnet. The same thing takes place when the two wires starting from the same post are perfectly insulated on the line, but the earth at the post is defective (too resisting): then only one portion of the current flows to earth, the other betakes itself to the second wire absolutely as if they crossed at the two points where the two conductors unite with earth. But when the two wires are parallel and near for a great length, and there is an induction by one upon the other—every time we work by one of them, each emission of current gives rise to two induced currents—one on closing and another on opening circuit. If these currents are strong enough, one of them will necessarily work the polarised electro-magnet. By joining the line wire successively to each of the extremities of the electro-magnet's wire, the apparatus will always act so long as transmission is effected by the neighbouring wire; on the contrary, there is only one extremity of the wire of the coils which can be joined to line so as to work the apparatus from a derivation current (or leak) between the two wires. We have thus, with an apparatus of this kind, a certain means of ascertaining whether, when the transmission sent on one of them affects the other, the influence is due to induction or derivation currents. The experiment, which consists in insulating the two wires at the opposite end, in sending a current upon one of them, and then observing a galvanometer placed in the other's circuit, is insufficient, because it does not give any indication relative to the derivations proceeding from a common bad earth.

In nearly all my experiments I made use of Hughes's instrument, an instrument which a suitable regulation will render very sensitive: the remainder of my experiments were made with other polarised electro-magnet instruments. Very sensitive galvanometers, whose deflection is almost instantaneous, such as Thomson's mirror galvanometer, may be serviceable for these studies in certain cases, but not always.

The first experiments were undertaken in 1869 on the underground line from Paris to Juvisy, at the time when it had just been constructed, and before it was connected with the aërial conductors. The cables of this line are 23 to 24 kilometres long, and the two smallest adjacent and parallel conductors are 8 millimetres from axis to axis. I first took the induced wire, and the inducing wire, in the same cable and contiguous one to the other, and I placed upon each of them at the Paris end one of Hughes's apparatus.

I considered separately the case when the two wires were to earth through large resistances.

In the first case when signalling on No. 1 wire, with a battery of 80 Daniell elements, the signal was recorded by the apparatus attached to the No. 2 wire, whichever end of the exciting coil was in communication with the line: the cause was therefore an induction one. When the battery was of 150 elements, the *induced* current represented the value of a 1 Bunsen element; that is to say, a 1 Bunsen element current sent along No. 2 wire produced the same effect upon the Hughes apparatus as did the induced current. These results ought not to be a matter of surprise, since, by reason of the wires' length and their condensing capacity, there are at the uninsulated extremity of the inducing wire very strong charges which develope currents on the induced wire, one of whose extremities is to earth.

ELECTRICAL NEWS,
August 12, 1875.

Duplex Telegraphy.

In the second case, which accords with practice, the other ends of the two wires were in connection with earth through resistance coils of 500 to 800 kilometres; and it was found that induction likewise took place which differed but little from that observed in the previous case. I was unable to ascertain what was the amount of induction at the second end of the wire; but it is nevertheless certain it must be inferior to that at the first end.

On taking two wires in two different cables, induction was still met with, but of much less strength.

In order to ascertain the influence of length upon the intensity of these phenomena I had the two wires, upon which I experimented, cut in halves. By operating as before upon the first half of these conductors, and upon two other conductors contiguous to one another, I found that the induction observed in the second case was greater than that observed in the first, but less than the double of that same induction. This shows that it increases with the length of the wires, but less rapidly than the length. In other respects I have been unable to determine the exact relation of these inductions.

The induction between two wires of one cable is relatively considerable, and this is a strong argument in favour of separating underground and tunnel wires in preference to having them bound up together.

Throughout my studies I have investigated the influence of the soil around a post upon the flow of electricity to earth, and its propagation on the wires terminating there. To get some idea of this influence, I replaced the inducting wire sometimes by a large condenser, and at other times by a different underground line wire going from the central post office to the Lyons Railway, in order to have no induction current between the two wires under experiment. A rheostat was placed between the earth and the point of junction of the battery's negative pole and the "earth knob" of the apparatus on the second wire.

Everything being thus arranged, the following results were obtained:—

(1). On sending a current into the first wire none was observed on the second wire, both of them being insulated at the other end, and without any rheostat resistance.

(2). When 35 resistance units were used, and a current from a battery of 150 Daniell's elements was sent on to the first wire, currents were set up in the second wire capable of working the apparatus, provided, however, its setting was more sensitive than is required for ordinary work. The induced currents would also work the instrument with its customary setting when a rheostat resistance of 180 units was employed.

(3). The extremities of the two wires being to earth, more striking results were obtained, for then the machine on the second wire worked with its ordinary setting from a current induced by a battery of 150 elements, and with only 30 rheostat units.

These results are easily explained by the theory of the propagation of electricity. They supply the means of finding out whether the earth at a post is good or bad. To ascertain this two condensers, or one condenser and a rather long underground wire, are required. The one condenser should be joined to a strong battery by a switch; the second should be joined up to the other pole of the battery through a very sensitive galvanometer or a polarised electro-magnet apparatus: both condensers should lead to different earths, the *latter* communicating with the earth around the post. If, when sending currents upon the first conductor, the apparatus on the second does not act, the earth around the post is good, for it must have too much resistance when the apparatus does act.

In the same year, 1869, I strove to ascertain whether any appreciable induction currents, inconvenient to the service, would be manifested between the aërial wires which were to be joined to the underground cables from Paris to Juvisy. For this object I erected one day in the signal house of the underground line, at Juvisy, when it was fine and the wires were well insulated, a Hughes apparatus on one of them, between Juvisy and Mâcon, which call A, to earth at Juvisy; and for more than half an hour I received in a perfect manner all the messages from Paris for Florence, effected by another wire, which call B, adjacent to that from Juvisy and Mâcon. On making the line current successively enter by each of the extremities of the coils, I assured myself that the currents which worked the apparatus were really due to induction, and were not derived. When Florence sent to Paris upon B, induction currents were found upon A, but they were much less feeble than when Paris sent to Florence. This can also be accounted for by the theory of the propagation of electricity. Between Paris and Mâcon there were upon the route of these two wires underground portions of about 1000 metres length; but previous experiments showed that the induction upon these portions could only have given very feeble currents: the observed induced currents could therefore have been almost due to the aërial parts of the wires alone.

In 1873 I resumed these experiments upon several wires, and notably on two wires (C and D) which were adjacent to one another upon the same posts between Marseilles and Lyons. Stationing myself at Marseilles and placing the instrument on C—disconnected at Lyons—I received (when the instrument was suitably arranged) almost all the messages from Marseilles for Paris sent on D wire. These experiments were made, first when the underground sections from Marseilles and from Paris were in the circuit of wire C, and again when these portions were cut out; the results were almost the same in either case. When Paris sent to Marseilles by wire D, the phenomena of induction were not appreciable in my apparatus.

It was likewise observed on cutting wire C successively at Valence and Avignon, that induction diminished with the length; for when the disconnection occurred at Avignon, scarcely any signals were obtained, as was expected from the results of previous experiments.

Journal de Physique. September 1875.

Some Experiments on Electrostatic Induction.—M. Govi.—These are to show that induced electricity of the first kind has potential. An electrified spherical body is supported under two pith balls, which are hung by linen thread from an insulated ring. At the very first the balls diverge, and the divergence increases when they are made to communicate with the earth. If this divergence (says M. Govi) arose from curvilinear induction by the inducing sphere, as has been supposed, it should cease or diminish, on the induction being suppressed; but this is not the case. On discharging the inductor with an uninsulated metallic point, the two pendula may be made to separate further. The reason is that the inductor, far from separating the balls by curvilinear induction, exercises on them an attraction which tends to bring them together. If we understand by *electric potential* the effort of electrified bodies to approach or withdraw from each other, the separation of the small pendula should still prove the potential of the induced electricity opposed to the inducing, were it even demonstrated that we must attribute it to what Faraday has denominated curvilinear induction. The potential of the induced electricity is still more distinctly manifested when the induced body is terminated by a fine point turned directly towards the inductor. If, in this case, the air being very dry, and the supports of the induced body perfectly insulating, the induction be allowed to act a few seconds, one finds that immediately after discharge of the inductor the induced body retains a perceptible charge of electricity of the same name with that of the inductor. All the other phenomena which have produced in some minds the contradictory idea of an induced electricity without potential are easily explained if we take into account the influence exercised on the inductor by bodies, insulated or not, which are brought near the induced.

Leçons sur l'électricité, professées en 1875-1876 à l'Institution royale de la Grande-Bretagne PAR JOHN TYNDALL, traduites de l'anglais par R. Francisque Michel.

Ce petit volume de 152 pages fait partie de la collection des actualités scientifiques. Il renferme un exposé très-clair, très-savant et très-amusant de toutes les expériences fondamentales.

M. John Tyndall s'est attaché à montrer que l'électricité est une science populaire, non-seulement parce qu'elle est à la portée de toutes les intelligences, mais encore parce qu'elle est à la portée de toutes les bourses. En lisant cet ouvrage que tous les gens un peu intelligents peuvent comprendre sans préparation spéciale, il est impossible de pas être frappé de l'immensité des ressources que l'électricité offre à l'éducation physique d'une nation civilisée.

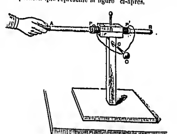
On se demande pourquoi les grands personnages officiels qui ont présidé à l'organisation de l'Exposition universelle ont opéré comme si l'électricité n'avait point encore été inventée, et s'il n'avait pas existé, il y a quelques années, un certain Franklin, un nommé Priestley, un Italien nommé Volta et des français dont les noms sont Ampère, Arago et Becquerel.

Le propre des abstracteurs de quintessence est d'apporter partout les ténèbres et les complications de leur esprit. Le vrai génie simplifie ce qui est simple et éclaire ce qui est lumineux.

La machine électrique dont se sert M. Tyndall a été imaginée par son préparateur, M. Cottrel, et construite pour ses leçons. Elle se compose d'un simple frotteur, comme on le voit par la figure suivante.

Ce frotteur peut être disposé sur un pied, de manière à produire un effet dans le mouvement en avant et dans le mouvement en arrière.

Cet appareil peut être rendu plus énergique à l'aide d'un tube qui permet d'utiliser la friction dans les deux sens, par une disposition que représente la figure ci-après.



d'un congrès international du génie civil, au nombre de ceux qui constitueront les huit groupes formant le programme d'ensemble officiel des conférences et congrès, pendant la durée de l'Exposition universelle.

Puisque l'Électricité n'a pas eu la faveur d'obtenir une petite place, pour elle toute seule, dans ces programmes officiels, nous croyons savoir que MM. les ingénieurs civils sauront lui accorder une compensation bien autrement précieuse.

Les neuf sections d'études et de délibérations entre lesquelles se répartiront officiellement les matières de ce congrès, comportent en effet bien des applications de l'électricité : son emploi dans les mines comme mode d'éclairage, d'avertisseur, etc., ses services sémaphoriques, les indicateurs du niveau d'eau, les avertisseurs des inondations, la transmission des signaux, les freins électriques, les nombreux usages qu'on fait de l'électricité dans les chemins de fer, l'éclairage des villes, des ports, des ateliers, etc., etc.

Espérons que la science et le progrès auront à enregistrer de nombreux et intéressants documents dans les comptes rendus des séances où tant d'habiles ingénieurs, dégagés de toute entrave officielle, seront certainement à même d'apprécier la puissance de l'électricité et l'importance des services qu'elle est appelée à rendre à leur art et à leurs travaux.

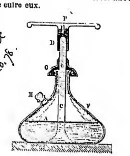
Un nouveau support isolateur

M. Mascart, professeur au Collége de France, vient d'inventer un nouveau support isolant dont l'emploi donne les résultats les plus satisfaisants pour toutes les expériences d'électricité statique.

Il se compose d'un flacon F, à goulot étroit, dans lequel passe la continuation tubulaire du fond C, d'un diamètre moindre de quelques millimètres que celui du goulot, de manière à réserver une certaine distance entre eux.

L'Electricité July 20. 78



Le haut de ce bâton de verre creux est résistant, afin qu'on puisse cimenter sur lui un tube de cuivre dans lequel on pourra visser quelque appareil, tel que le disque de la figure ci-jointe, une sphère, une traverse dans un anneau, etc. Sur le côté, en haut de la bouteille, est un autre goulot B, formé avec un bouchon de verre usé à l'émeri, par lequel on peut verser d'abord de l'acide sulfurique que l'on renouvellera de temps en temps. Comme l'espace entre le bâton creux et le goulot de la bouteille est très-petit, l'air dans la bouteille ne change

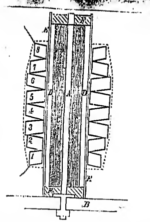
[20398.]—Strength of Induction Currents.—In order to solve the difficulty of A. B. C. and D. I must premise that the strength of any current, whether of electricity or water, is directly proportional to the whole quantity of stuff transmitted, and inversely proportional to the time in which it is transmitted: so that we can write C equal $\frac{Q}{T}$. Now Masson and Breguet have proved that precisely the same quantity of electricity is set going in the secondary coil when the primary circuit is made, as when it is broken. This is also roughly indicated by the experiments of A. with a galvanometer. Further, the time during which the current lasts depends on the rapidity of variation of the primary current. If this were slowly increased, or slowly diminished, the same quantity of electricity would be set in motion in the secondary wire as if it varied quickly; but the strength of its current (which varies inversely with the time) would be very much weaker. Now in a coil the primary current does increase somewhat slowly on making contact, by reason of the opposing extra current it sets up, and which has full liberty to circulate so long as the circuit is closed. But when the circuit is broken, the direct extra current meets with a break in its circuit, and though it manages to leap over a little (producing a bright spark), yet it is considerably checked; moreover, the express function of the condenser is to prevent even this passage as much as possible. It must now be apparent that the induced currents produced by make and break respectively, are of very different strengths. In fact, while one is not competent to break down any but the smallest air-resistance, the other can leap an inch or two. But if a well-conducting circuit is afforded through a galvanometer or voltameter, for instance, both currents will pass; and, as their quantities are equal, they will produce the same effect, whether of deflection or decomposition. Indeed, the current which lasts the longest time will have a better chance over the galvanometer needle; it will, moreover, be less able to leak away in a long circuit. The fact that the current passes principally in only one direction through vacuum tubes, is indicated by the different appearances of the two ends, which appearances are reversed on the reversal of the current ...

NOVEMBER 27, 1875.]

A NEW INDUCTION COIL.

Mr. C. F. Brush, M. E., communicates to the *Engineering and Mining Journal* a description of a novel induction coil designed by him, an engraving of which, in section, we give herewith. The three eighths inch iron rod, A, is secured by a collar and nut in the base, B, and serves as a support for the core, C, which is composed of about 1,200 iron wires (No. 20 gage) made perfectly straight and carefully annealed. This core is covered by four layers of paper saturated with paraffin, then one layer of the primary wire, D, which is of copper one eleventh inch in diameter and 90 feet in length, then six layers of paper, and, finally, the second layer of wire. The latter is not covered but is wound with a narrow strip of paper between the consecutive turns, the object of this being to economize space. A hard rubber tube, E, incloses the primary wire, and is 12 inches long, 2¼ inches in internal diameter, and ¼ inch thick. It is held by the pieces of wood, F, which also support the core. The secondary wire is 30,000 feet in length, is wound in eight sections, 1, 2, 3, 4, etc., and covers 8 inches of the tube, as shown. Sections 1 and 8 contain 35 layers of wire each; sections 7 and 2, 55 layers each, and sections 3, 4, 5, and 6, 67 layers each. This arrangement places most wire around the middle portion of the core, where its inductive force is greatest. The consecutive layers of wire in each section are insulated from each other by ten thicknesses of unsized paper saturated with melted wax; and the consecutive turns of wire in each layer are insulated from each other by being wound with a space of one two-hundredths of an inch between them. The wedge-shaped space between the sections is filled with paraffin, which insulates them, and the exterior of the sections is also covered with the same material, until the shape of the apparatus becomes as shown. The secondary wire begins with section 1, and forms the outside layer first; thence it passes from layer to layer until the innermost one is reached, then it crosses over to section 2, where sections 1 and 2 touch each other, and forms the innermost layer of section 2, thence from layer to layer until the outside one is reached; thence it passes to section 3, forming the outside layer first, and thus it proceeds until it ends in the outside layer of section 8.

19



The advantages of this arrangement, as regards economy of space, is obvious. No insulating material being required between the sections, where the wire passes from one to the other, none is used. But as the quantity of wire, and consequently the tension of the induced electricity, increase directly as the distance from this point toward the opposite edges of any two contiguous sections, so the thickness of paraffin increases until finally it is thickest of all where insulation is most needed. A space of one eighth of an inch between the innermost layer of the sections and the tube, D, is filled with melted paraffin, which, together with the rubber tube itself, forms the insulation between the primary and secondary wires.

The object in using the secondary wire bare is economy of space. It is a matter of the greatest importance that the whole of the secondary wire be placed as near as possible to the magnetic core, E, as the inductive force of the latter varies inversely as the square of the distance from its axis. The same amount of silk covered wire would occupy at least double the space, and would, consequently, average a much greater distance from the core.

The condenser used with this coil consists of two hundred and forty sheets of tinfoil, five by ten inches, arranged in the usual manner, and separated by single sheets of varnished paper. The break piece is Foucault's automatic, in which the rupture of the current occurs at the surface of mercury covered by a layer of absolute alcohol. It is operated by a separate electro-magnet, which, however, is in connection with the primary wire of the coil. The instrument is provided with a commutator by which the primary current is started, stopped, or reversed at pleasure.

The performance of this coil is quite extraordinary for an instrument of such small size. When operated with two cells of Bunsen's battery, it gives sparks three and a half inches in length; and with one large cell of the Grenet battery, three inch sparks are obtained. The sparks are very dense, and are attended with numerous and brilliant ramifications.

20

[23029.]—Sole of Electrophorus (Q.Q.).—When the cake of resin is flapped with catskin its upper surface becomes charged with negative electricity, which does not pass to the cover when in contact, owing to the non-conduction of the resin, but acts inductively on the neutral electricity of the cover, decomposing it, attracting the positive to the under, and repelling the negative to the upper surface. The negative electricity of the upper surface of the resin acts by induction on the neutral electricity of the under, attracting the positive and repelling the negative, which passes into the earth. The positive electricity on the under binds the negative on the upper surface. The reaction between the electricities on the under and upper surfaces causes more electricity to be excited by the action of the form or metallic surface on which the resin rests. By insulating the form the charge is diminished. If the upper surface of cover is touched while in contact with cake of resin, the free negative electricity passes off, and the cover becomes charged with positive electricity.—Hugh Clements.

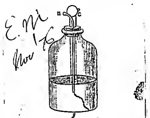
ECHANIC AND WORLD OF SCIE

IMPROVED FORM OF LEYDEN JAR.

[11807.]—The following improved form of Leyden jar may, perhaps, interest some of your readers:—In addition to the ordinary form of Leyden jar there is attached a hollow brass cup, C, cemented into a glass tube. This tube passes through the wooden disc which forms the cover of the jar. A communication is formed between C and the internal coating by a brass wire, terminating in the knob D. This wire does not extend quite to the bottom of the jar, but the lower part of tube is coated with tinfoil, which is in contact with the wire, and extends to the inner coating of the jar. At the bottom of the jar a hook is provided by which a

E. M.

Nov 76



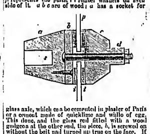
chain may be suspended so as to form a communication between the external coating and other bodies. When a jar of this kind is once charged, the wire may be removed, or allowed to fall out by inverting the jar, in which case the jar will remain charged, since no communication exists between its internal and external coating, and, as the internal coating is protected from the contact of the external air, the absorption of humidity is prevented. It will be seen that by the above arrangement an electric charge may be transferred from place to place, and kept for a considerable time.

Charles Winkolmann.

Auckland, New Zealand.

[28723.]—Winter's Electrical Machine.—The axle is better when made of glass, with wooden cheeks in centre to carry plate. Two short pieces of brass tube may be cemented on to glass axle. Just where it works in the wooden uprights you might make some journals of arbor vitæ to carry tubes.—W. J. Lancaster.

[28723.]—Winter's Electrical Machine.—I think, as far as regards results, it makes little or no difference which of the two ways mentioned you mount the plate. Mine is fitted up on the plan last named, and it works very well. I send a sectional sketch of the mode of mounting I adopted, in which p represents the plate, i i rubber washers on each side of it. a b c are of wood; a has a socket for



glass axle, which can be cemented in plaster of Paris or a cement made of quicklime and white of egg. This done, and the glass rod fitted with a wood gudgeon at the other end, the piece, b, is screwed on without the bolt and turned up true on the face. If a and b are made in one piece it is extremely difficult to fix the glass axle at right-angles to the face at b. The bolt is afterwards put in, the whole put together, screwed up, and placed in a pair of temporary bearings, in which it can be rotated, and the plate set to run true. It can afterwards be ground smooth on the edge on a grindstone. The gudgeon, d, runs in a wooden bearing, which incloses the end of the bolt and nut, so that there be no tendency to form convection currents in the air from the sharp angles on them. The sketch is to a scale of one-fourth for a 21in. plate.—J. B., Belfast.

[28723.]—Winter's Electrical Machine.—To insure more perfect insulation "Mir" had better have the axle entirely of glass, while the support nearest the handle should be of strong wood, screwed firmly into base of machine; the other support should be of glass, carrying on the top a piece of wood, in the side of which a hole must be bored to receive the

March 23, 1877. ENGLISH ME

end of axle; the plate must be fixed nearest to the glass support, while a good space is left between the plate and the wooden support.—Courtenay B. Gray.

[28087.]—Winter's Electrical Machine.—1. One end of the wire should be connected. 2. Yes; well polished. 3. Same diameter as plate works well. You can make it larger if you like, but I prefer plate and ring to have equal diameters.—W. J. Lancaster.

77

New Dielectric Constant.—M. Neyreneuf.—On continuing the comparison of different isolating substances employed as the dielectric plates of a condenser, the author has established that for glasses of the same nature the ratio $\frac{e}{n}$ of the thickness to the number of sparks corresponding to a given quantity of electricity was constant. He has almost determined the value of this ratio for the varieties of glass met with in commerce. For substances much more isolating—such as ebonite, caoutchouc, and paraffine—the above ratio, which may be called the condensing constant, goes on increasing in a marked manner with the thickness. Consequently only results obtained with plates differing respectively little in thickness are comparable.

77

NEW HOLTZ ELECTRICAL MACHINE.

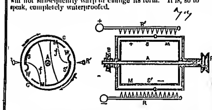
By Professor Elihu Thomson.

The many advantages possessed by induction electric machines, over those producing electricity by friction, have caused the latter to be almost entirely discarded as a source of static electricity. Of these induction machines, the "Holtz" is, perhaps, the best known, and many modifications of this machine have been designed to render it self-charging, and constant in action. When, however, the plate form is adopted, the limit to the size of the revolving plates, with the ordinary materials and space that can be allotted, is soon reached. With glass plates the speed of running is limited by the fragile nature of the glass itself.

The form of Holtz machine presently to be described, it is believed, obviates these and other disadvantages, and affords at once a cheap, compact, and portable piece of electrical apparatus, capable of being run at a very high speed, and greatly increasing the electrical power of the machine.

The materials used in the construction are chiefly paraffined wood, and paper or cardboard, also paraffined. When wood or paper is thoroughly dried or baked, and, while still hot, immersed in melted paraffin at above 100° C. until soaked, it becomes, after cooling, one of the best non-conductors of electricity known. The wood so treated is very strong, and will not subsequently warp or change its form. It is, so to speak, completely waterproofed.

77



In the figure, C C is a hollow revolving cylinder of paraffined paper or cardboard, the ends being made of the same material, or of wood similarly prepared. This cylinder is revolved about a *fixed* axis, A, by the pulley P. The axis A is fixed to the frame of the machine at B, and is made of paraffined wood or other insulating material. It serves as a support for the stationary inner cylinder, M M, also of paraffined cardboard. The cylinder M M carries on its inner surface one or more pairs of what are commonly known as sectors or inductors, S S', consisting of strips of partially conducting material, placed opposite the outside rows of collecting points R R', and provided with the usual pointed projections turned toward the inner surface of the revolving cylinder C C. Parts of the inner cylinder M M, adjacent to the sectors S S', are cut away in a direction from S S' opposite to the direction of rotation of the outer cylinder. These open spaces are seen at W W. The open spaces or windows, W W, are not necessary, if the contour of the inner cylinder be that shown by dotted lines, *f f*. The supports for the various parts, as above described, are all thoroughly paraffined to insure complete insulation. The metallic collecting points or combs, R R', constitute the conductors or poles of the machine, + and — respectively, or the reverse, the polarity depending on the original charge given to the machine. The charging is accomplished by holding an electrified body, as a rubbed piece of caoutchouc or vulcanite, opposite one of the spaces or windows W, as shown at E, at the same time that the cylinder C C is in motion, in the direction shown by the arrow.

The machine may be made self-charging by providing a small accessory cylinder, revolving opposite the points E, on an axis parallel to that of C C. The accessory cylinder is made of hard rubber, shellac, sulphur, or the like, and is constantly rubbed by an amalgamated cushion, as in the common frictional machine.

A machine constructed as above, with the cylinder about 7 inches diameter and 12 inches long, and run at a moderate speed, gives enough electricity to charge three 1 gallon Leyden jars to a tension of 1 inch in less than four seconds, and may be employed for every purpose where an abundance of static electricity is required.—*Franklin Journal.*

VOLPICELLI'S NEW THEORY OF ELECTRO-STATIC INDUCTION.

June 77

An insulated conductor charged with either kind of electricity acts on bodies in a natural state placed near it in a manner analogous to that of the action of a magnet on soft iron, that is, it decomposes the neutral fluid, attracting the opposite and repelling the like kind of electricity. The action thus exerted is said to take place by influence or induction. The usual apparatus for demonstrating this hypothesis is a brass cylinder placed on an insulated support and provided at its extremities, or at various points along its length, with pith balls suspended by linen threads. If this arrangement be placed near an insulated conductor charged with either kind of electricity, the natural fluid of the cylinder is supposed to be decomposed, and free electricity is developed at each end, when both pith balls there located will diverge. The electricity of opposite character to that of the conductor goes to the end of the cylinder nearest that conductor, while electricity of the same kind as the conductor seeks the further extremity. Where is a point on the cylinder where no divergence of the pith balls occurs, and this is termed the neutral point.

This hypothesis was, some thirty years ago, attacked by Melloni, who asserted that the imaginary electric fluid was not separated into its positive and negative components, but that both of the latter existed all over the cylinder, although, in point of quantity, there was more negative fluid on the end nearest the positive conductor and more positive fluid on the opposite extremity. The difference between Melloni's theory and that first noted will be clear from the annexed engravings. If the inducing source, c, Fig. 1, is positively electrified, all the negative fluid of the cylinder, A B, according to the old hypothesis, goes to a m b, and all the positive fluid to a n b, a b being the neutral point. Melloni's idea is exemplified in Fig. 2, where both kinds of electricity exist in some degree over the entire cylinder. Melloni had scarcely more than reached a definite conclusion on this subject when he died; but his work was taken up by M. Volpicelli, who for some twenty years has pursued the necessary investigations, and has recently announced conclusions confirming those of their original enunciator.

Fig. 1.

Fig. 2.

M. Volpicelli's apparatus consists of a large glass tube, 70 inches long, terminated by metallic armatures, and containing a dry pile composed of 21,000 disks closely packed together and covered with a layer of copper on one face and of peroxide of manganese on the other (Fig. 3). This battery works uniformly for several months, and is a constant source of electricity. The body on which the induced electricity is developed is an ordinary glass cylinder, perfectly isolated by threads of raw silk, by which it is suspended in the crotches of a support (Fig. 4). The electricity rendered free by induction is taken on the cylinder by means of a little proof plane, which merits a special description; for the success of the experiments is largely dependent upon the excellence of the instruments used and the care with which all possible causes of error are avoided. The plane is composed of two small disks of copper, 0·85 inch in diameter, separated by a thin layer of insulating varnish. One of these disks is in communication with the soil by means of a metallic rod which is held in the hand. The other disk is fixed to a metallic rod terminating in an ivory ball, which slides freely in an opening situated in the middle of the first disk and in an eyelet carried by an annexed arm. In order to use the device, the two disks are brought into contact, and the movable disk is placed on the cylinder. The free electricity on the surface of the latter condenses on the disk, and may be transported to a distance, as, for example, upon the exterior armature of an electroscope, situated far enough away from the dry pile not to be influenced by it. M. Volpicelli also uses a proof plane consisting simply of a pin head. A portion of the end of the pin is cut off, and the rest inserted in a knob of sealing wax at the end of a metal handle. A Böhnenberger electroscope, containing improvements devised by M. Volpicelli, is also used. The two plates, towards which the gold leaves, D, are attracted when the exterior armature, A, is electrified, are supported by two glass columns containing dry piles analogous to those of the large inducing cylinder (Fig. 5). This electroscope has great sensibility. It might be termed a kind of electrical microscope.

Fig. 3

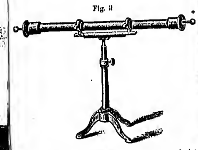


Fig. 4.

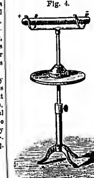

Fig. 5.

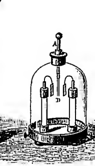

In order to make the experiments, the insulated cylinder is properly placed in view by the electric source. It becomes electrified by induction. The free electricity on the cylinder is collected by the proof plane; and with the charge plane the electroscope is touched. The following phenomena then appear:

1. The free electricity found on the portion of the cylinder nearest the electric source is of the same character as that of the latter. This is diametrically opposite, of course, to the assertion of the old theory. The experiment may be repeated five or six times successively.

2. If the cylinder be placed in communication with the soil, so that the free electricity is allowed to escape, and the experiment with the proof plane be again tried, no sign of electricity is manifest.

3. If the cylinder be moved away from the electric source, so that the influence of the latter is diminished, and the proof plane be applied, the electroscope to which the latter is touched indicates an electricity of opposite character to that of the inducing body.

M. Volpicelli sums up the result of his investigations as follows: "Upon an insulated conductor submitted to the influence of an electrified body, electricity of opposite name possesses no potential. It is found in greatest quantity at the end of the conductor nearest the electrified body, and diminishes towards the opposite end. Electricity of the same name as that of the electrified body is found at all points on the insulated conductor, the end nearest the electrified source not excepted. It increases as it approaches the other extremity, and is always free." We extract our engravings from *La Nature.*

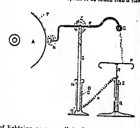
Zigzag Sparks.

With a view to finding the cause of the peculiar zigzag form taken commonly by electric sparks, especially those of the Holtz machine, in air, Professor Tait, of Edinburgh, has recently had a number of photographs of such sparks prepared. These sparks were produced partly in ordinary air, partly in the free air one or two feet above the flame of a strong Bunsen burner, partly in a wide glass tube, into which air was passed through a long iron tube, heated to a dark red glow. The general result of the examination is that the zigzag form depends on something which heat is capable of removing from the air. This is, therefore, not water vapor, nor is it very small drops of water, for even falling water drops were inactive, except that they produced simply an interruption in the photographed sparks. It is probably, the author thinks, organic substances which, as Schiller and Pasteur have shown, would be kept away from the apparatus by a cotton stopper as well as by direct combustion.

An improved form of electric machine, similar to that of Holtz, but much more powerful, has been devised by the Russian physicist, M. Teploff. The paper armatures occupy a space of 105 to 120 degrees, and are cut in a complicated way. Besides the two usual combs there are four others, two of which are placed opposite the posterior extremities of the armatures, and the other two towards their anterior extremities, a little above the collecting combs. Conductors covered with guttapercha connect the posterior comb of the first armature with the anterior of the second, and reciprocally. Two or more Leyden jars of average size replace the collecting tubes of Holtz. The power of the machine seems to depend on the extent of surface of the Leyden jars and the form of the armatures. The author varies the latter in each example of the machine till the maximum action is obtained. He has succeeded in producing sparks of all colours by retarding, more or less, the discharge, by introduction between the exterior armatures of the two jars, or between their inner armatures and the collecting combs, of medium conductor such as bands of coloured paper, wet cords, leaves of various plants, &c.; each matter produces a special modification of spark. One may also use jars, the armature of which are formed of paper or even of water. The red and yellow sparks easily inflame tow, carbonised wood, and lycopodium, but the blue sparks do not. Aug 77.

LEYDEN JAR DISCHARGE 10 INCHES OR MORE IN LENGTH.

[13460.]—Having seen from time to time in the English Mechanic questions relative to the length of spark it is possible to obtain from a charged Leyden jar, and having devoted a considerable share of attention to the matter, with a fair amount of success, I beg to submit to the notice of the readers of the English Mechanic a method by which I succeeded in producing a vivid steel-blue spark, or flash, 10in. or more in length, and of the apparent thickness of an ordinary slate pencil. The discharge is attended with a sharp explosion very different from, and much louder than, that obtained ordinarily from a Winter's machine, and is as much like a flash



of lightning as can well be imagined. Ordinary electrical sparks of very great length (20in.) have been obtained from frictional machines before; but, as far as I can ascertain, no condensed discharge of the length of 10in. has been before noted. I believe that by taking some precautions which have since occurred to me, and by a slight alteration in the arrangement of the apparatus, the usually considered limit (the distance between the rubber and the collecting points) will not prevent me from getting sparks from a Leyden jar 20 to 30in. in length. My experiments have, however, been stopped rather abruptly for the present by the fog and rainy weather; but as soon as the dry frosty weather makes its appearance, I shall immediately resume them, and, if successful, will most likely communicate the results to our readers—with the Editor's permission. I will now describe the apparatus employed, which, as will be seen by the diagram, is nothing more than a long, narrow Leyden jar, slightly modified to suit this particular purpose. The ordinary prime conductor is altogether removed, and in its place I put a glass tube, B, 33in. long, 1in. thick, and 1½ internal diameter, hermetically sealed at one end. This is silvered throughout its whole length internally by the patent silvering process, and this film of silver forms the internal coating. It is supported in the upright position by the wooden stand, C, which is 1in. thick, and into which it slides easily to the distance of a foot, and on the outside of the upright part of this wooden stand, between the lines N' N', is slipped a piece of thin brass tubing, D. This forms the outer coating, and is in metallic communication with the rod of the spark-drawer, P, by means of the wire, x.

E is a hollow ball of alder wood, 3in. diam., saturated with paraffin wax, and made to fit tightly on the glass tube, at its upper and open end. F is a thick brass wire passing through the ball, as shown, and terminating at one end in the 2in. brass ball, G, and at the other end in the usual collecting comb, which is protected by a wooden shield, H, saturated with paraffin, and which terminates at each end in a 2in. wooden ball, also paraffined and set back, as shown by the dotted line, K. The wire, F, is placed in metallic connection with the internal coating by pushing into the tube a tuft of very fine hard-drawn brass wire, M, and allowing the upper end to press against F, as shown at L. The brass spark-drawer, P, is 3in. diam., and highly polished, and slides easily into the wooden stand, Q; while its distance is regulated by the screw, s. I may mention that to prevent, as far as possible, any loss of electricity, the wire is covered throughout its length with caoutchouc tubing, and the external surface of glass tube is varnished with solution of shellac.

A is the cylinder of machine, and T the silk flap. It will be seen by the above description that it is almost impossible for the electricity to be drawn off by the surrounding bodies, as happens in all cases where the ordinary form of prime conductor is used, and the tendency to burst through the glass tube is overcome by the wooden coating, C, which, being an imperfect conductor, acts, as it were, like a spring or buffer. This apparatus can be employed in all cases in which the usual form of P. C. is used, and by its means vacuum tubes can be as brilliantly illuminated as with a 14 or 15in. spark induction coil, as I have proved by trial. The cylinder of my machine is 15in. long, and 12in. diam. For smaller cylinders, I should recommend a glass tube of same length as above, but of ¾in. diam.

J. Reynolds, L.R.C.P., &c., &c.

Cold Harbour-lane, East Brixton,
Oct. 21. 77

A Condenser of Variable Capacity.—This condenser, as described at the meeting of the Physical Society, November 14, was stated to have been designed for use in connection with the Holtz electrical machine, to show the effect of condensation on the length of the spark. It consists of a test-tube coated externally with tinfoil to form the inner armature, and a glass tube enclosing the test-tube, and having its outer surface covered with tinfoil for the outer armature. The inner tube can be slid out or in along the length of the external tube, and the capacity thereby varied. Professor Guthrie shewed that a spark from the Holtz machine could by its means be gradually reduced. ~~Nov 78~~ Dec 78

Effects of Planté's Rheostatic Machine.—The effects produced by the rheostatic machine which we described a short time ago in the Telegraphic Journal, are, says M. Planté in a note to the French Academy of Sciences, similar to those from electric machines and induction coils, but present certain points of dissimilarity worthy of mention. M. Planté studied them by means of machines composed of 10, 30, 40 and 50 mica plates charged with a secondary battery of 800 couples. With a ten plate machine making 15 turns per second, a series of brilliant sparks from 13 to 14 millimetres long were obtained, succeeding each other at the rate of 30 per second, accompanied with a crackling sound. On turning the machine slowly, so that few sparks passed, they became very sinuous, and when the machines with 30 and 40 plates were employed, these sinuosities raised and lowered themselves above and below the straight line jointing the discharge points. But on quickening the speed of the machine the track of the spark became more constant for each position of the points. When the points were inclined to each other at an obtuse angle, the spark issued in a track of fire straight from the positive point, raised itself above the negative point, and curved towards in a hook which displayed numerous sinuosities. The brushes formed by the discharge, when the distance between the points are increased by 1 or 2 millimetres, take the same course. The length of the sparks appear to increase in simple proportion to the number of condenser plates. Owing to the greater

A Wandering Electric Spark.—G. Planté.—The condensers of mica which enter into the construction of the rheostatic machine are sometimes perforated when too slender under the action of a current of 800 secondary couples, just as is the glass of an overcharged Leyden jar. This accident enabled the author to observe a very curious fact, which consists in a slow and progressive movement of the spark, which the author shows in an illustration. Sept 78

dessus toute la Méditerranée grâce à la visibilité possible de temps en temps d'une côte à l'autre. L'autre vérification se fera par le réseau italien qui, grâce à diverses îles bien placées se rattache directement aux triangles tunisiens. C'est ainsi que la prévision si hardie de Biot et d'Arago sera réalisée et que l'Afrique sera réunie sans interruption au système anglo-français et franco-espagnol.

Expériences sur les fers nickelés ou météoritiques. — Nous sommes admis à l'honneur de lire un mémoire relatif à la reproduction artificielle des alliages météoritiques de fer et de nickel. Notre méthode consistant à réduire à la chaleur rouge par l'hydrogène par le mélange des chlorures des deux métaux. Elle nous a fourni à l'état de pureté le *tænite*, le *kamacite*, etc. Nous avons pu aussi obtenir divers alliages associés en un ensemble qui, traité après polissage par un acide, donne les figures de Widmannstætten. D'autres essais ont eu pour résultat de recouvrir des fragments rocheux de ces mêmes fers nickelés et même d'empâter dans ces métaux des grains de péridot ou des morceaux de dunite. Le produit avait alors tous les caractères des météorites remarquables dont le fer de Pallas est le type le plus connu et il résulte de ces faits que ces masses cosmiques représentent sans hésitation possible de vraies brèches de filons concrétionnés. L'analogie qu'on peut établir entre elles à ce point de vue et les filons terrestres ajoute un nouveau terme à la série des arguments qui conduisent à reconnaître une grandiose unité dans les phénomènes géologiques dont les diverses parties du système solaire sont le théâtre.

Élection. — La séance est terminée par la nomination d'un membre dans la section de médecine et de chirurgie en remplacement de Claude Bernard. La liste de présentation discutée lundi dernier en comité secret portait : En 1re ligne : M. Gubler, en 2e, M. Charcot, en 3e, M. Marey, en 4e M. Paul Bert et en 5e M. Moreau. Les votants étant au nombre de 59, M. Marey est élu par 40 suffrages, M. Paul Bert est désigné par 15 bulletins, M. Charcot par 3 et M. Gubler par 1.

ÉTINCELLE ÉLECTRIQUE AMBULANTE

Les condensateurs à lame de mica qui entrent dans la construction de la machine rhéostatique[1] se percent quelquefois, quand les lames de mica sont trop minces, sous l'action du courant de 800 couples secondaires, de même que le verre d'une bouteille de Leyde trop fortement chargée par une machine électrique. Cet accident m'a donné l'occasion d'observer un fait très-curieux, qui consiste dans une marche lente et progressive de l'étincelle électrique, et permet d'assister au développement successif de ses capricieuses sinuosités.

L'un de ces condensateurs étant posé sur un plateau métallique isolé, en relation avec un des pôles de la batterie secondaire, si l'on touche l'armature supérieure avec l'autre pôle, une étincelle éclate sur un des points du condensateur où le mica est trop

[1] *Comptes rendus*, t. LXXXV, p. 794, et t. LXXXVI, p. 701. *La Nature*, 6e année, 1878, 1er semestre, page 15.

THE "SINGING CONDENSER" has recently re-appeared at Paris, where it is generally introduced as an invention of Mr. C. Varley instead of Dr. Wright. In a description of Reiss' receiving telephone, given in 1867 in Ferguson's *Electricity*, the following passage occurs:—"Suppose a person to sing a note at the mouthpiece which produces 300 vibrations a second, the circuit is broken at the bladder 300 times, and the iron wire ticking at this rate gives out a note of the same pitch. The note is weak, and in quality resembles the sound of a toy trumpet. Dr. Wright uses a receiving apparatus of the following kind:—The line current is made to pass through the primary coil of a small induction coil. In the secondary circuit he places two sheets of paper, silvered on one side, back to back, so as to act as a condenser. Each current that comes from the sending apparatus produces a current in the secondary circuit, which changes and discharges the condenser, each discharge being accompanied by a sound like the sharp tap of a small hammer. The musical notes are rendered by these electric discharges, and are loud enough to be heard in a large hall."

This was the last word on telephony in 1867. Nine years later the speaking telephone was invented, and we hear a great deal on the subject to-day; but yet they had done something then which should not be overlooked.

Expériences faites au Laboratoire de la Société libre d'Emulation du Commerce et de l'Industrie de la Seine-Inférieure sur le Condensateur chantant.

1re Expérience :

Influence de la forme du condensateur sur la puissance des sons rendus.

J'ai essayé de renforcer les sons émis en donnant au condensateur une forme tubulaire et en faisant passer un courant d'air dans l'intérieur; le résultat a trompé mon attente, une étude plus approfondie m'a montré qu'il ne pouvait pas en être autrement; en effet, les deux parties du condensateur, situées aux extrémités d'un même diamètre du cylindre ainsi constitué, sont tellement disposées, que leurs actions se détruisent réciproquement. Or, comme le fait est vrai pour un diamètre quelconque, il en résulte que le faible chant qui se produit n'est que la différence qui existe entre deux actions de sens contraires qui, en pratique, ne peu-

vent être rigoureusement égales. La démonstration théorique complète est très-facile, elle serait néanmoins trop longue pour prendre place ici, la démonstration expérimentale sera plus concluante.

Voici comment on peut la réaliser devant un nombreux auditoire :

Je découpe des rubans de papier d'étain de 0m 10 cent. de large sur un mètre environ de longueur.

Je prépare des lames isolantes de 0m 14 cent. de largeur sur 1m 10 de longueur environ.

J'emploie, comme lames isolantes, du papier à calquer, passé dans de l'essence de térébenthine; j'en ai toujours obtenu de bons résultats et sa préparation ne présente aucune difficulté.

Je superpose les lames isolantes et les lames conductrices et je les fais communiquer à la manière ordinaire (voir le no 13, 5 octobre); j'obtiens ainsi un condensateur étroit et très-long, six feuilles métalliques suffisent.

Si je le fais fonctionner dans ces conditions, j'obtiens un chant d'une certaine force.

Relevant alors les deux extrémités du condensateur, je donne à tout le système la forme d'un U; le chant est reproduit avec une intensité d'autant moindre que les deux branches verticales sont plus rapprochées.

Comme contre-épreuve, je replace le condensateur dans sa forme primitive, le chant retrouve aussitôt son intensité première.

Il vaut mieux, dans cette expérience, remplacer la voix humaine par un diapason électrique, la régularité y gagne beaucoup.

L'explication est simple; il est facile de voir que dans les deux branches verticales du condensateur en U, les lames sont disposées en sens inverse, et que l'induction doit les ramener à l'état neutre; la seule partie active est la base, sensiblement circulaire qui n'est point compensée.

Enfin, si j'enroule le condensateur de façon à en former un tube de 0m 14 cent. de hauteur environ et de 0m 20 cent. de diamètre, je rentre dans le cas considéré en premier et l'explication précédente peut encore s'y appliquer. Nous pouvons, en effet, prendre aux extrémités d'un même diamètre deux surfaces assez petites pour pouvoir les considérer comme planes; dans ces deux surfaces, la disposition des feuilles sera inverse et l'effet nul ou à peu près.

2me Expérience :

Etant donné un condensateur mis en activité par un diapason électrique et émettant une note constante, ce condensateur donnera en plus du son fondamental invariable toutes les notes de la gamme, si on approche de lui une lame de substance quelconque métallique ou non dont on fera varier convenablement la distance.

Je réalise l'expérience de la manière suivante :

Un condensateur peu serré de trente-deux feuilles 24 / 12, actionné par une bobine de 0 07 centimètres, est animé par un diapason électrique, il rend un certain son que j'appellerai son fondamental.

Le condensateur est mis à plat sur une table; si j'approche de lui une feuille de verre ou une plaque métallique de surface légèrement plus grande que celle du condensateur, je ferai naître immédiatement, en plus du son fondamental, un son plus faible qui, si je rapproche de plus en plus la plaque du condensateur, passera par toutes les notes d'une gamme chromatique de deux octaves environ.

Le son est d'autant plus aigu que la lame inductrice est plus voisine du condensateur.

Toute la gamme s'obtient par un déplacement de 0m 10 à 0m 15 cent.

Ce chant, que j'appellerai secondaire, paraît suivre la loi des vibrations des cordes, car l'octave aiguë d'une note s'obtient en réduisant de moitié la distance qui sépare la plaque du condensateur et la quinte des deux tiers. Avec un peu d'étude, je suis parvenu à exécuter des airs très-simples et populaires qui ont été immédiatement reconnus.

Le phénomène qui donne naissance à ce chant secondaire doit être très-complexe, car si, au lieu d'une plaque, nous en prenons deux et laissant la plus voisine du condensateur immobile, nous éloignons ou rapprochons la plus distante, nous obtiendrons encore une modification du son. Si enfin, plaçant le condensateur verticalement, nous disposons deux plaques parallèlement à chacune de ses faces, nous obtiendrons deux notes dans un rapport quelconque, harmonique ou non, plus le son fondamental.

Il y a là, certainement, un phénomène nouveau au point de vue électrique et même au point de vue acoustique; car,

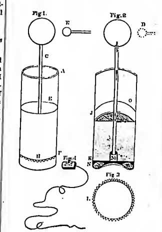
THE ELECTRICAL CONDENSER.

THE condenser has of late years assumed so great a degree of importance as an essential auxiliary in practical telegraphy, especially in the working of submarine cables, and of duplex, quadruplex and automatic apparatus upon land lines, that the following communication, which was published as far back as 1841 in the first volume of the *Practical Mechanic and Engineer's Magazine* of Glasgow, Scotland, will be found of considerable historical interest. It illustrates an important step in the transition of the device from the well-known Leyden Jar which was the earliest form of the condenser, having been discovered by Muschenbroek in 1746, to the modern construction of interleaved plates so arranged as to expose a very large inductive surface. The author of the communication, Mr. Thomas Taytor, is at present connected with the Department of Agriculture at Washington, D. C., and has kindly favored us with a copy of the original publication:

To the Editor of the Practical Mechanic and Engineer's Magazine:

SIR.—I send you, for publication, a drawing and description of an improvement on the construction of the Leyden jar; and which, from experience, I find adds very materially to the power of that instrument. The principle upon which the increase of electric power which I find my jar contains, depends upon increasing the internal surface, and facilitating the escape of the fluid from the outside. The following description, with the annexed diagram, will, I hope, make the construction sufficiently apparent:

Fig. 1 is a perspective view of the jar, and fig 2 its section. A, fig. 1, is a glass jar, twelve inches high and five wide, coated with tin-foil, inside and outside, in the usual manner, up to E. H is a collar, or hoop of common tinned iron, two inches broad, half an inch of which is bent over, so as to form a horizontal flange, nicked all round like the teeth of a saw, forming points for the escape of the electric fluid from the outside surface of the jar. This collar or hoop is fitted tightly on the jar, at the bottom, as represented at H F. L, fig. 3, is a ground view of this tin hoop, the nicked flange only being visible. C, fig 1, is a wooden pillar, about an inch thick, and twenty-two inches long, supporting a wooden ball, about 4½ inches diameter, hollow, to render it lighter, and both covered with tin-foil. This ball receives the electricity from the prime conductor of the machine E, and conducts it to the interior of the jar, which is filled with a series of metallic plates. In the jar which I have constructed there are 100 of these metallic discs, which may be formed of tinned iron, black sheet-iron, tin-foil, or the thin sheets of lead with which tea-chests are lined, which last is preferable, as being cheap and easily cut. Having cut the discs or plates to the size of the jar, with a hole in the centre, sufficiently large to admit the passage of the wooden pillar, they are laid one upon the top of the other, but kept from touching by a disc of cotton net, cut the same size and shape, and placed between them. The 100 plates in my jar, made in this way, and bound together by strong paper pasted round the outside, are about 2½ inches in thickness, when in the jar; but I think that by increasing the number of plates, the capacity of the jar will likewise be increased. To prepare the jar, plaster of Paris must be poured in to make the bottom level, as represented by the light lines at the bottom of fig. 2. A small iron tube M, to receive the pillar, is soldered upon an iron plate, K, which plate is tacked on to a piece of wood, N, and being imbedded in the plaster of Paris, fits and is fixed in the bottom of the jar. The metallic discs, represented by the lines above K, are then placed in the jar, and the pillar being fitted in the tube M, the apparatus is



complete. The line J O, Fig. 2, is the top of the tin-foil coating. The electric fluid coming from the prime conductor D, descends the pillar, as shown by the direction of the arrows, and is diffused over the plates. Fig. 4 is a small piece of wood covered with tin-foil, to which a chain is attached. This being placed in contact with the hoop H, when giving any person a shock, all danger of pulling over the jar is avoided.

It will be perceived that by this arrangement there is a vast increase of surface in the jar; and so great is the increase of power, that the jar in my possession, constructed in the manner described, gives a shock equal to a battery formed of nine jars the same size, and coated in the usual manner.

Any further results worth notice which I may discover, I shall be most happy to communicate.

I am, sir, yours,
THOMAS TAYLOR.

2

THE DISRUPTIVE DISCHARGE.

After describing, in *La Nature*, the large induction coil constructed for Mr. W. Spottiswoode, President of the Royal Society, by Mr. Apps, M. Alfred Niaudet makes the following remarks:—

"We ask permission to conclude with an observation resulting from our own personal experience, and which we think may be novel. It is a well known fact that longer sparks are obtained between a point and a plate than between two points. It seems to us easy to explain why the former arrangement should be the best. Everybody knows that the sparks by no means pass in a straight line, especially if the distance they traverse is considerable. They follow a sinuous and capricious path, no two sparks taking the same path, or completely resembling each other.

"The path taken by the spark must be that of least resistance, and, in consequence of the motion of the air or small changes of the surface of the electrodes, this line of least resistance is constantly changing. If now we offer to the spark a somewhat extended metallic surface, such as that of a plate, the spark will not always follow the normal which is geometrically the shortest line. It often takes an oblique direction in which, by reason of almost unappreciable variations, the resistance of the air may be reduced. In popular parlance we might say that the plate offers to the spark a greater number of paths than would be offered in the case of two points, and amongst these paths that of least resistance is never the shortest.

"The peculiarity in the resistance of air is also met with in other bad conductors, and notably in glass. If we examine a plate of this material which has been pierced by the spark, we may see that the path is never a straight line, and sometimes branches may be observed which end in the substance of the glass, and which the electricity would seem to have abandoned after having essayed a passage in their direction."

Electrician Feb. 21 1880

FOUR LECTURES ON ELECTROSTATIC INDUCTION.

1 JAN. 16, 23, 30, AND FEB. 6. 77

BY J. E. H. GORDON, B.A.

(Assistant Secretary of the British Association).*

LECTURE I., JAN. 16.

"Amongst the actions of different kinds into which electricity has conventionally been subdivided, there is, I think, none which excels, or even equals, in importance that called *Induction*. It is of the most general influence in electrical phenomena, appearing to be concerned in every one of them, and has in reality the character of a first, essential, and fundamental principle. Its comprehension is so important that I think we cannot proceed much further in the investigation of the laws of electricity without a more thorough understanding of its nature. How otherwise can we hope to comprehend the harmony and even unity of action which doubtless governs electrical excitement by friction, by chemical means, by heat, by magnetic influence, by evaporation, and even by the living being?"

So, forty-two years ago, wrote the Master whose memory is honoured wherever the study of natural laws is loved, and whom in this place we should more especially remember, as the Royal Institution was his home and workshop during all the best years of his life. Need I add that the passage I have just read is from the "Experimental Researches of Faraday?"

The subject of our study to-day and in the other lectures of this course will be such of the laws of induction as are now clearly known. I shall first endeavour to show you what the term induction means, and what is the problem about it which for fifty years students of nature have been trying to solve. The problem is partly solved now, but much remains to be done. It will, I think, be pleasant to follow the stages of discovery up to to-day, and perhaps to look a little forward and try to see what the discoveries which may some day be made may lead to.

First, we have the simple phenomena of induction and electrification, some of which I shall shortly show to you.

The unsolved question, "What is electricity?" we shall not attempt to touch upon. It is sufficient for our purpose to know that when a body exhibits certain properties it is said to be electrified, or to be in a state of electrification. We also know how to produce this state at will, but we know next to nothing of its nature. We do not know whether the properties of an electrified body are caused by one or two electric fluids entering it or leaving it, as water into a sponge; or by a motion of its molecules, as when a body is heated; or by a strain or twist of its structure, as when steel is magnetised.

We have no conception of electricity apart from the electrified body; we have no experience of its independent existence. Let us now begin the study of certain phenomena of electrification which it is necessary for us to understand before commencing the study of induction.

If we rub a piece of sealing-wax or glass with a silk handkerchief we find that it has the power of attracting light bodies, as you see. The glass or sealing-wax, after being rubbed, is found to be in the state called "electrification."

When I hold the electrified body near these light paper shavings, the action takes place from the sealing-wax *across the intermediate air*. What is the nature of the action? We do not fully know yet, but it is called *Induction*.

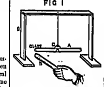
This is only one form of induction, but I shall hope to show you others. Meanwhile, note the following definition to begin with.

Every electrified body from which no electrification is allowed to escape has a particular action on all neighbouring bodies, and this action is called induction.

Before we go any further in the study of induction we must inquire, Is there any difference between the electrification produced by rubbing sealing-wax and that produced by rubbing glass? We may answer at once that there is, and the difference is a very curious one, namely, that the properties of the two kinds of electrification are exactly opposite to one another. By opposite I mean this: if by any means equal quantities of the two electrifications be added together, they will exactly neutralise each other, or, in other words, adding a quantity of one kind of electricity is the same as taking away an equal quantity of the other. There are a great many ways of producing electrification, but all electrification is of one or the other kind, either that of glass or that of sealing-wax. For convenience, glass electricity is called + sealing-wax electricity —. Here I have an electric machine, which is simply a convenient method of rubbing glass and silk together.

I have shewn you one form of induction, namely, the attraction of light bodies by an electrified body. Let us now examine the effect of electrified bodies on each other. Here I have some pieces of sealing-wax and glass, and a means of suspending any one of them. We find that sealing-wax repels sealing-wax, glass repels glass, glass and sealing-wax attract each other, or, generally, like electricities repel, unlike attract. Hence you see that there is always a force acting between electrified bodies, and that, when the electrifications are alike, it is a repulsive force, when different, it is attractive.

FIG 1



This force acts through the air or *other substance* between the electrified bodies, as you see when I put this plate of paraffin between the suspended rod and the one in the hand. It is therefore, a form of induction. What is the machinery which conveys this force across the air or paraffin? This is a question to which we shall attempt to give a partial answer later on.

Conductors and Insulators.—In certain substances, such as metals, electrification is able to move freely; that is, if one end of a metal rod receives electrification, the electrification is at once *conducted* to every part of it, as you may here see.

The proof plane being applied to the end furthest from the machine, it is found to be electrified. These substances are called conductors. In other substances electricity is not able to move freely, and if one end is electrified, the other remains in an unelectrified state, as may be seen by substituting a glass rod for the metal one in the preceding experiment. The electricity being *insulated* at the first end, these substances are called Insulators. It is possible to insulate a conductor by placing it on a glass stand, and we can then study the movements of the electricity in it without the latter being able to escape.

FIG 2

We are now in a position to study the effect of the induction of an electrified body upon a conductor near it. Here is our conductor L, and we will place it near the charged knob K of the electric machine. The jumping up of these paper slips shows that the metal is electrified, but no electricity has passed to it, and it is electrified by induction. Thus we learn that by induction an electrified body electrifies bodies in its neighbourhood. This metal rod is electrified, although no electricity has been transferred to it. Let us now examine what difference there is between the electrification produced in this rod by *conduction*, or direct transfer of electricity, and by *induction*. First let us electrify the rod by conduction, and let us, after stopping the machine, test both ends with the proof plane. We see that both ends are *positively* electrified. We have stopped and discharged the machine, but the electricity remains in the cylinder, and will remain there until some conducting path is opened for it, as by touching it with the finger. The actions are just as if a portion of an electric fluid had been forced from the machine to the cylinder, had distributed itself all over the latter, as water finds its own level, and had now been drawn off through my body as water through a pipe. Let us now return and examine the parallel induction phenomena. We see by the attraction of the papers that the cylinder is electrified at both ends. Let us now examine what kind of electricity there is at each end. We find, first, that the end nearest to the machine is —, the far end +. We now see why electrified bodies attract light objects; they first induce on the side nearest to them an electrification opposite to their own and then attract it. Let us now stop the machine. All signs of electrification disappear. Thus we see, when electrification is produced by induction, there is nothing analogous to the transfer of fluid from the machine to the cylinder. It is more as if, to use a bold simile, by some straining force the cylinder was distorted into an electrified state, and, just as when we distort a plastic substance, any increase of length is accompanied by a corresponding decrease of thickness, so that the volume remains the same. So, when we electrically distort a cylinder by induction, every increase of electrification at one end of it, that is, any appearance of + electricity, is accompanied by a decrease of electrification at another part, that is, on appear-

FIG. 3.

FIG 4

FIG 5

* Delivered at the Royal Institution 1879.

of — electricity. The most rigorous and accurate experiments have shown that these two quantities, viz., the increase and decrease of electrification in a body, when acted on inductively, are exactly equal. I can show you a rough experiment to illustrate this point. I have here two gold leaf electroscopes, which are exceedingly delicate machines, for detecting small quantities of electricity.

FIG. 6

We now again electrify the cylinder by induction, and by means of the proof plane transfer a little electricity from each end to the electroscopes respectively. We now stop the machine and remove the cylinder. Each electroscope remains charged, one + and one —, and each with a charge whose strength is proportional to the induced charges on the two ends of the cylinders respectively. If these charges are equal, they should neutralise each other when I connect the electroscopes, and you see they do so. The reason why it is so important that we should see clearly that equal quantities of both kinds of electrification are always produced by induction is that this experimental fact shows us that the action of induction is to produce something analogous to a distortion of the electrified body, and that, if this were not the case, but a greater quantity of one kind of electricity than another was induced, it would show that something had been added to or taken from the induced body, and the action would be more analogous to a change of bulk than to a distortion of molecular shape. The problem, then, that we have before us is: "Given the known experimental facts which we have just been considering; given that there is an action, which we call induction, across air and other insulators from an electrified body to other bodies in the neighbourhood; that the induction causes these attractions, and repulsions, and "inducings" of electrifications which we have spoken of, what is the machinery by means of which this induction acts? What is the nature of the lever, the rope, or the pushing pole, which strains, and pulls, and pushes across the air, or glass, or other non-conductor which we place between the induced and inducing bodies?" We must attempt to answer these questions bit by bit, and our first attempt shall be based on the difference between Induction and Conduction.

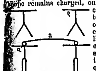


FIG. 7

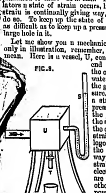
We have seen that when a piece of glass or other insulator is placed in contact with the conductor of an electric machine it is thrown into a state of strain and distortion, but that the electricity does not escape through it. When, however, a metal or other conductor takes the place of the glass, there is no appearance of such a state of strain at all. What is the explanation of this? It is this. Equally in conductors and insulators a state of strain occurs, but in conductors this state of strain is continually giving way, while in insulators it does not do so. To keep up the state of strain in a conductor would be as difficult as to keep up a pressure of steam in a boiler with a large hole in it.

Let me show you a mechanical experiment in illustration—only in illustration, remember, not in explanation, of what I mean. Here is a vessel, U, connected to the water pipes at one end and to a pressure gauge, S, at the other. There is no escape for the water, it cannot flow or move, and the gauge shows a considerable pressure. I now turn the tap, and allow a stream of water to escape. The pressure and strain is relieved and the gauge falls; that is, as soon as the state of constraint gives way and the current flows, it is seen that the strain no longer exists. In the analogous electrical case, bodies in which the state of constraint easily gives way do not show the phenomena of strain or induction, but allow the electricity to flow freely, and these are called conductors; while, on the other hand, bodies which have a great power of resistance to the straining force can be greatly strained without allowing a current of electricity to flow. These are called insulators or non-conductors. When such a body is subjected to a powerful straining or inducing electric force it exhibits the phenomena of strain or induction very strongly. Let me now show you an experiment illustrating what I have just stated.

FIG. 8



You remember that when we placed the insulated cylinder near the machine the induction which took place charged the near end — and the far end +. In this experiment we are only concerned with the near end, and we will lengthen our cylinder so as to get the far end out of our way. How are we to do this? This is a large room, and no doubt we might, at some considerable trouble and expense, so lengthen the cylinder that we could remove its other end to a distance of some 20 or 30 feet. But we can do better than that. We will make the whole world part of our conductor. The earth, owing to the water in it, is a good conductor. We will connect this wire from the cylinder to the water pipes, and now we have one end of our conductor on the table and the other safely out of our way somewhere in Australia.

FIG. 9.

Now you see there is air in the space between the machine and the cylinder, and the state of strain will commence as soon as I begin to work the machine, as you see by the divergence of the gold leaves of the electroscope when I take the proof plane from the cylinder to it; in other words, electricity is induced on our end of the conductor.

This induced electricity will remain here during the action of the machine as long as the air or other insulator is between the plates; that is, as long as the substance between the plates resists the straining force, so long will the state of strain be kept up. If, however, I connect the plates by some substance which offers an exceedingly small resistance to the straining force, as this metal bar, the state of strain at once gives way, and all induction ceases, and no divergence of the electroscope can be obtained. The electricity at the same time flows away, and distributes itself in the earth. This experiment is somewhat analogous to the mechanical one I showed you, where the strain was relieved by opening a tap and allowing the water to flow away.

The particles of glass move more freely over each other when hot than when cold, and hence we should expect that hot glass would yield more easily to a straining force than cold glass would. The following experiment shows that this is the case. Here is a glass flask containing mercury, and set in a dish of mercury. The mercury inside is connected to the electric machine, and that outside to the earth. On working the machine it is found, first, that no electricity can escape through the flask; secondly, that there is a strong induced charge on the mercury outside. Now let the mercury be made hot. It heats the glass, the particles move more freely over each other, the glass yields to the straining force, electricity escapes through it, and at the same time all induction ceases.

FIG. 10.

We have, in this lecture, by various means produced electricity, and we have produced sometimes one kind, and sometimes the other. It is important to examine whether we can actually produce one kind alone. If this were possible, we might actually increase the quantity of electricity in the world. Experiment shows us that we cannot do this. For every bit of + electricity that we produce we produce an exactly equal quantity of —. We cannot make or destroy electricity; we can only strain bodies so that their two ends shall show opposite electrical properties. When we rubbed glass we produced + electricity on its surface. Was not that a creation of electricity? No, for an exactly equal quantity of — electricity was produced on the rubber, as I can show you. (The rubber, on being laid on the electroscope, caused a strong divergence of the leaves.) To show that this — is equal to the +, a very simple experiment will suffice. I rub this sealing-wax till, by the cracking, you can hear that it is highly electrified, but do not remove the rubber from it. You see there is no effect on the electroscope. The reason is that the action of the — on the rubber exactly balances that of the + on the sealing-wax.

In the electric machine itself equal quantities are produced, only the rubbers are connected to the earth, so the — escapes, and only the + is kept. Here is the machine placed on an insulating stand, and a wire from the rubber brings the — as well as the + to the conductor. I work the machine, and you see even the gold leaf electroscope shows no sign of electrification. This shows that equal quantities are always produced. But when we rub sealing-wax and silk, and put down the silk on the table, the — electricity escapes to the earth, and is neutralised and lost, and we have to all appearance + alone in the wax. No; for the instant the balancing — is removed, the +, by induction, produces a fresh — on all surrounding bodies. It does so then, and not till then, as we may see by making one of those neighbouring bodies the electroscope, while the rubber, if it is not discharged, but removed, induces + on bodies near it. No electrification of one kind only can be produced any-

where. If we charge a balloon +, and send it up as high as possible, it will still induce an equal opposite charge on whatever is nearest to it, be it earth, clouds, or clear air. We have no means of knowing how much or in what way the earth itself, with its atmosphere, is charged; but this we know, that, whatever its charge may be, it will induce an exactly equal opposite one on the moon, the sun, and even the most distant stars.

Ignored Facts in Electricity.

At a meeting of the New York Academy of Sciences, Prof. C. A. Seeley, in a paper entitled "Ignored Facts in Electricity and Magnetism"—fully illustrated by experiments—showed that scientists and the text books misrepresented the phenomena of static induction. It is commonly asserted that if a soft-iron bar be brought near a magnetic pole, the bar becomes a magnet with two active poles, and a point of neutrality between them located at the middle of the bar. It is stated that if an insulated conductor be brought near a prime conductor it becomes electrified, so that the minus electricity occupies the half of the conductor contiguous to the prime conductor, and the plus electricity the remote end, with neutrality between the two halves. But on testing the statements by experiment, it will be found that the induced magnet has only one kind of active magnetism, which is of the same name as that of the inducing pole, and, moreover, that it is pretty evenly distributed over the mass of the bar; it is practically a magnet with a single pole. Similarly, the free electricity of the insulated conductor is plus and pretty evenly distributed. The actual facts are susceptible of simple and unequivocal demonstration. A compass-needle, when carried along the bar, or put in any position with reference to it, turns constantly to the bar with the same pole; iron-filings are attracted all over its surface, etc. The condition of the electrical conductor may be shown by pith balls or other simple electroscopes. The facts as here stated concerning electricity might have been inferred from the ordinary theory. One kind of electricity attracts its opposite, but in the act or condition of attraction the electricities are of necessity bound in such a way that they cannot have any external influence; the external influence of the bound electricity implies a relationship which is inconsistent with its existence as induced electricity. The case of the induced magnet is of peculiar interest, because it makes it manifest that there is here a form of magnetism hitherto unrecognized, namely, magnetism—which moves and comports itself like a fluid. This induced magnetism, as to the *rationale* of its production, its distribution, and its disappearance, is so remarkably like induced static electricity as to suggest the probability that they will be found to be phases of the same thing. The facts here brought to light are related to the fundamental notions of electricity and magnetism, and it cannot be doubted that they will be of importance to science and the useful arts.

Étude des phénomènes d'induction. — M. Gaiffe dépose sous forme de pli cacheté une note concernant quelques expériences d'induction; il signale avec quelle facilité on peut étudier chaque phénomène d'induction à l'aide du galvanomètre de Thomson. Cet instrument lui a permis de constater qu'après la fermeture du circuit, il se produit deux courants successifs dans le fil induit: le premier, relativement fort et de courte durée, dirigé dans un sens; le second faible et de longue durée, dirigé en sens inverse. FOUR LECTURES ON ELECTROSTATIC INDUCTION.

JAN. 16, 23, 30, AND FEB. 6.

BY J. E. H. GORDON, B.A.

(Assistant Secretary of the British Association).*

LECTURE III. (CONCLUDED FROM PAGE 100.)—JAN. 30.

SPECIFIC INDUCTIVE CAPACITY.

We now turn from the mathematical diagram to the actual instrument. Here you see we are hampered by many troublesome conditions; we have not only to say, "Let *a b c d e* be plates in such a position," but to support them in that position without the supports interfering with their action, not only to say, "Let them be insulated," but to make sure that no electricity escapes, and again we have not only to say, "Let the dielectric be removed and replaced," but to provide means for removing it. You see we must not put our fingers in between the plates when the apparatus is in action.

Well, here is the apparatus (Fig. 23), as it grew up in the course of three or four months' labour. Four of the plates, viz., *b c d e*, are supported from brass stages, carried on brass pillars. Each plate hangs by a thin steel rod, which is rigid enough to move the plate a little out of the vertical, if required for adjustment. The upper end of each steel rod passes through a hole in the stage, and is attached to the centre of a little ebonite triangle, *e*, which rests on the stage by three levelling screws at its angles. By means of these screws the plates can be adjusted to be exactly parallel with each other. When the plates are adjusted, they are clamped by screws, which come down upon the triangles from the stage above. The wires connected to the steel rods lead from each triangle to the binding screws *f f*, by which wires from other instruments can be attached to them.

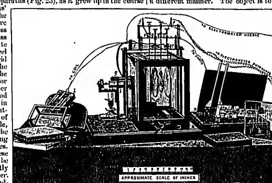

FIG. 23.

The remaining plate, *a*, is supported differently. An ebonite block is fixed at the back of it, and this is fixed to a brass rod, *b*, about an inch thick of the shape ▽ and about six inches long. This slides in two V shaped grooves in two brass pillars *b*, and is pressed down into them by springs. It is moved by a very delicate screw, with a specially contrived spring collar, to avoid "back lash," as it is called, that is to ensure that the motion of the plate reverses at the same instant as the motion of the screw head is reversed. A scale is engraved on the sliding rod, and a vernier on one of the supports. This scale is read to 1-1000th inch by a telescope fixed on the case of the instrument behind *g* (it cannot be seen in the engraving). The scale is illuminated by a candle.

The dielectrics *k k* are made seven inches square, and their thickness varies from ¼ inch to 1 inch.

The slide for inserting and withdrawing the dielectrics is shown, *c d*, in the picture. It moves in guides, and can be pulled in and out by the square handle without opening the case, or disturbing the experiment in any way. The three other handles are for adjusting the position of the dielectric, one moves it parallel to itself by means of a rack, one turns it round a vertical axis by a tangent screw, and the third round a vertical axis by screwing in or withdrawing a wedge under one side.

The callipers *m* shown in the same figure are for measuring the thickness of the dielectrics, and for adjusting the plates parallel to each other. For this latter purpose they are laid on the hinged bracket *n* which can be fixed to a socket at the back of the apparatus.

In work all the upper stage which contains the connections of the plates receiving the induction is enclosed in a metal box connected to earth, the wires leading to the electrometer are enclosed in a metal tube, and the electrometer itself is in a metal case. The reason of this is to protect these parts of the apparatus from accidental induction from the connecting wires, &c. If from any accidental cause the earth connection is interrupted the effect is at once seen in the uncertain and irregular behaviour of the instrument. The metal cover first used for the upper stage is shown. It was made of card and tinfoil. A brass one is, however, now used instead of it.

Before going any further I must express my obligations to Mr. Kieser, of the firm of Elliott Brothers, for the admirable way in which he has constructed the instrument from my drawings. The electrometer is of the ordinary Elliott pattern quadrant described by me in the last lecture in the account of Hopkinson's experiment.

The source of electricity is a large induction coil by Apps, having twenty-two miles of secondary wire (Fig. 24), which, with a suitable battery and break, is capable of giving a seventeen-inch spark in air. In these experiments it is, however, used in a different manner. The object is to obtain a moderate electrification, very rapidly reversed, and to ensure that the positive and negative electrifications should have equal strengths.

When a coil is worked in the ordinary way, although the same quantities of electricity are produced both on making and breaking the primary, yet the arrangement of the currents is such that the current produced in one direction on breaking will produce a much stronger external effect than that produced in the other direction on making. To obtain equal electrifications in the two directions it is necessary to use a very large coil, a very small battery, and a very rapid break. In these experiments the current in the coil primary is only that of ten small Leclanché cells. The rapid break is shown in Fig. 24, and also on a larger scale in Fig. 25. It consists of a little electro-magnetic engine. The scale of inches in Fig. 25 shows the size. One electro-magnet is fixed, and another revolves. A commutator is so arranged that the force between approaching poles is always attractive, and that between poles which are moving apart repulsive. When worked by four quart-sized Grove cells the flywheel of this engine revolves just 100 times per second. You see the whole engine is not more than eight inches long and four high and broad, but when I set it in motion the hum and vibration are felt all over the building. In the rim of the flywheel, which is about two inches diameter, are 60 slits cut, into each of which is let a piece of ebonite. A light spring presses on it, and the primary current on its way from the Leclanché battery to the coil has to pass from the spring to the wheel. It is thus broken 60 times and closed 60 times in each revolution of the wheel. At each break a current is induced in one direction in the secondary, and at each make one is induced in the other direction. Thus there are 120 alternating currents induced every revolution of the engine, or, as the engine turns 100 times per second, 12,000 each second.

The engine does great credit to its maker, Mr. Apps.

To test the equality of the currents in the two directions, the secondary poles were connected to a small vacuum tube. No effect whatever was produced on the light by reversing the primary by means of a commutator between the engine and the Leclanché battery.

One of the secondary poles of the coil is connected to plate *c* of the induction balance and the other to the plates *a* and *e*, and of course the electrifications of every part of the balance and electrometer are reversed with those of the coil poles. The strength of the electrification is such that a spark could be obtained between the coil poles of from 1-25th to 1-50th of an inch; that is, it is about equal to the direct charge of 2,000 silver cells.

In case, however, the sum of the make and break electricities should not be exactly equal, the machine, Fig. 26, was introduced

* Delivered at the Royal Institution 1879.

ON THE MINUTE MEASUREMENTS OF MODERN SCIENCE.

By Alfred M. Mayer.

Article XVII.

On the Application of Rotating Mirrors to the Measurements of Minute Lengths, Angles, and Times.

ON WHEATSTONE'S EXPERIMENTS TO MEASURE THE VELOCITY OF ELECTRICITY AND THE DURATION OF THE ELECTRIC DISCHARGE.

In our first article we stated that this series would end with two remarkable *applications*, in which the various methods and instruments described in this series would be

Fig. 51

combined and brought to bear on problems whose solution, at first sight, appears beyond human power. The two problems which we have selected from the extensive array found in the annals of science are: The Measurement of the Velocity of Electricity and the Duration of the Electric Discharge, and the Measurements of the Wave-Lengths of Light. In giving accounts of these problems I will show how men of science have discovered, minutely examined, and measured actions of physical forces which take place in a space less than the 1-10,000th of an inch and endure but a few billionths of a second. Such actions are the flash of the electric discharge and the undulation of a wave of ether in a beam of light.

In 1834 Charles Wheatstone, of London, read a paper before the Royal Society which marks an era in the history of experimental physics. He then first described the application of the rotating mirror to the examination of the nature and duration of phenomena which last but a few thousandths or millionths of a second. This paper of Wheatstone had more effect on the progress of science, from the publication of the method of observing and measuring with the rotating mirror, than by reason of the new facts in the nature of electricity which it gave to the world, though the latter were at that time of the first importance.

The first new application of the revolving mirror was proposed by Arago in 1838. With it he proposed to measure the relative velocities of light in air and in water, and thus to decide whether light in its nature is the rapid translation through space of very minute particles of matter, or whether it is of the nature of undulations or pulses, rapidly transmitted through a rare and highly elastic medium, which must be supposed to exist throughout the universe. If light be of the nature first described it must move more rapidly through water than through air; if of the nature of undulations of an elastic medium, it must move less rapidly in water than in air.

We cannot do better than here let Arago speak for himself on this subject. The following is what he said before the Academy of Sciences of Paris, at the meeting in which he proposed this experiment:

"I propose to show how it is possible to decide, unequivocally, whether light be composed of little particles *emanating* from radiant bodies, as Newton supposes, and as the greater part of modern geometers admit, or whether it is simply the result of the undulations of a very rare and very elastic medium, which physicists have agreed to call *ether*. The system of experiments which I am about to describe will no longer permit, it seems to me, to hesitate between these two rival theories. It will decide, *mathematically* (I use designedly this expression)—it will decide, mathematically, one of the grandest and most debated questions of natural philosophy.

"Besides, my communication is the fulfilling a sort of engagement to the Academy I accepted at one of its last secret sittings.

"I discussed the admirable method, by the aid of which Mr. Wheatstone attempted the solution of the problem of the velocity of electricity over metallic conductors. I had hardly enumerated the important results obtained by that ingenious physicist, when several of our members, whose

Fig. 52

names are authority in such matters, stated that my report was far too appreciative. 'In supposing it well determined, the inferior limit assigned by Mr. Wheatstone to the velocity of electricity will not have,' said one, 'any marked influences on the progress of the sciences; besides, limits of the same order, and even more extensive, can be deduced indirectly from various electric and magnetic phenomena. As to the method of the revolving mirrors, it does not seem to be susceptible of application, but to the simple questions already studied by the inventor.' I tried to refute this last opinion. I believed myself that the new instrument, suitably modified, would lead to results that Mr. Wheatstone was not aware of. I already foresaw that, even in supposing it inclosed in the narrow limits of a small room, it could serve to measure the comparative velocities of light moving through air and through a liquid. I was not slow to learning, and without having hardly the right to be astonished or to complain, that my assertion had been received with incredulity. Nevertheless, I intend to vindicate it to-day in all its parts."

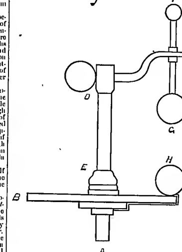
Arago then enters into the most minute details of all the parts of the experiment. The velocity of rotation that can be given to the mirror, the visibility of the image formed by light after having traversed the necessary length of liquid, the possibility of reducing that length of liquid, or the velocity of rotation of the mirror by employing simultaneously several rotating mirrors from which the light would be successively reflected, and also in substituting for water bisulphide of carbon, which acts more powerfully on the velocity of light, are, on his part, the objects of a thorough examination. After the publication of this remarkable communication no one could doubt the success of the experiment which it so carefully and so minutely described.

Failing sight and the infirmities of age prevented Arago from ever putting his proposed experiment to actual test, but, presenting his method to his younger scientific brethren to work out, it was reserved for the talented and lamented Foucault to have the honor of solving the experimental problem with an apparatus similar in principle to that proposed by Arago, but simpler in construction and more precise in its measures. With apparatus Foucault first proved that light moves *slower* in water than in air, and thereby gave to the undulatory theory of light one of its main supports.

The following is the letter, in which Foucault gave the first news of the success of this noble and ever-memorable experiment:

"To the Editor of the *Journal des Débats*—Sir: I will not wait for the expiration of the fortnight to give you an account of what most occupied the Academy of Sciences during their meeting of yesterday. All knew that M. Arago was to continue the account of his beautiful researches in polarization and photometry. The attendance was large, and the Academy recorded at its session a foreign associate and two corresponding members—Sir David Brewster, Lord Brougham, and M. De la Rive, of Geneva. But

Fig. 53



WHEATSTONE'S WHIRLING APPARATUS.

what was not expected was, that M. Arago recalled attention to one of the most beautiful projected experiments that the genius of a savant has ever produced, and he declared that, after having conceived it, he had left to the young generation the care and the honor of performing it. The experiment has more than once occupied the attention of the Academy; it proposes to decide, by means of a revolving mirror, whether light moves faster in air than in water, and to seek, in the probable result of this experiment, the confirmation of the theory at present adopted to explain all optical phenomena. You may judge, Sir, of the emotion with which I heard this generous declaration—I, who for several days had in my hands the experimental solution of this great problem! Nevertheless I thought it proper to postpone to the next meeting the reading of the paper in which I have recorded my results. In the meantime permit me, sir, to announce, in a few words, the results which I have observed.

"Light employs more time to run over the same path in water than in air, and the time which it takes to traverse these two different media is shown by the deviation of a ray which is reflected at a given moment from a mirror revolving with a great velocity. All things remaining equal, the deviations were found to be proportional to the indices of refraction of air and water. It is not possible to entertain the least doubt as to the reality of these results; they have been obtained by two different methods. The two deviations were first observed successively, and were found unequal for the same velocity of the mirror. They were then observed simultaneously, which rendered the observation still more certain.

Léon Foucault."

In 1862 Foucault added various improvements to his apparatus, and brought its measurements to such precision that he measured the velocity of light with accuracy.

"This is an admirable experiment in physics, in which, by the power of intellect and manual skill, he succeeded in not only rendering sensible, but even measurable, the time employed by light to run over a path of 20 meters, although this time barely equals the 1-15,000,000th of a second. . . .

"We would be unjust if we did not mention that the success of the experiment of Foucault was greatly indebted to Froment, the able constructor of the various parts of the apparatus. The clockwork which gave to the toothed disk a uniform motion of one revolution per second, and the revolving mirror put in motion by the little air-turbine or siren, ought to take rank among the numerous mechanical wonders which have proceeded from his hands. The most ingenious conceptions remain unrealized if they do not find an artist capable of executing them. Thus history has taken care to treasure the memory of eminent mechanicians, to whom are due the delicate constructions which have given important progress to science. The name of the illus-

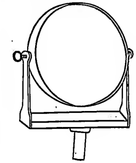


Fig. 54.

trious English clockmaker, Graham, remains forever associated with the discovery of aberration and nutation, made by Bradley with an instrument constructed by that artist; in the same manner the name of Froment will remain inseparable from the beautiful and refined experiment of which we have just spoken, and for which he constructed the important and ingenious improvements added by Foucault to the original apparatus devised by Arago."*

In like manner the name of Joseph Saxton should ever remain associated with Wheatstone's celebrated experiments with the revolving mirror, for to the skill of this eminent American mechanician Wheatstone was indebted for the construction of his apparatus and for valuable assistance given him during his experiments with it. Also, it is not improbable that the fact of Saxton's having previously used the revolving mirror in the examination of phenomena of momentary duration may have suggested to Wheatstone the application of the revolving mirror to the investigation on the velocity of electricity and the duration of the electric discharge. This investigation we will now proceed to describe.

It will render easier the understanding of Wheatstone's experiments by prefacing our description of his work with a fact or two in physiological optics which lie at the foundation of his method of experimenting.

Imagine a minute bright spark, or *dot* of light, which appears but for an instant—say that it lasts only the 1-100,000th of second. The eye, of course, can receive light from this spark only during that minute interval of time, yet the *sensation* produced by the light from the spark lasts much longer; so that after the spark has really ceased to exist the eye perceives the spark as existing. The duration of this *apparent existence* of the spark depends on the intensity of its light, and may last from 1-10th of a second to over a whole second of time. It is therefore evident that the unassisted eye can never determine the actual duration of flashes of light which have minute periods of existence; for in a series of sparks, all of the same intensity of light, and whose durations extend from 1-100,000th of a second to one-half of a second, the eye will see each spark, lasting the half of a second, if this is the duration of the sensation of light of the intensity of the sparks.

The eye, therefore, has to call in instrumental aid. This is afforded by some contrivance which will move either the spark *or its image*, and if the spark has a duration at all comparable to the time during which it has been moved, it will be drawn out into a line which has its length in the direction in which the spark or its image has been moved. Thus, for example, suppose that the spark is a mere *dot* of light—not a line—and has lasted 1-100th of a second, and that during this 1-100th of a second the spark was moved from

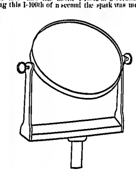

Fig. 55

right to left through one inch. Then, on account of the persistence of the sensation of light on the eye, the spark will appear as a horizontal line of *one* inch in length. If the velocity of the motion of translation remains the same and the spark lasts only a fraction of 1-100th of a

* See "Essay on the Velocity of Light," by Delaunay. Translated by the writer and published in Smithsonian Report, 1864.

Wheatstone is shown in Fig. 55. The reflecting surface of this mirror is inclined to the axis of rotation and nearly perpendicular to it. If a luminous point be placed anywhere in the prolongation of the axis of rotation it will be reflected, so that by the rotation of the mirror and the persistence of visual impressions, it will appear in a smoky room as a luminous cone, and the base of this cone will appear on the ceiling as a luminous ring, forming a circumference of a circle, whose center is on the axis of the mirror prolonged. In this form of experiment the angular velocity of the image is equal to that of the mirror, and both move in the same direction.

Wheatstone thus describes his experiments with this mirror: "The flame of a candle presented to it appears as a broad luminous ring; the image of the sun is converted into a magnificent fiery belt, etc. A series of minute sparks made to pass between two points, or between a point and the prime conductor of a machine, presents to the eye, from the rapidity of their succession, the appearance of a permanent star of light. When this star is placed in the prolongation of the axis of the revolving mirror, the successive sparks of which it consists are reflected to the eye, each from a different part of the surface, and they are exhibited arranged at regular distances in a circle. When the intermissions are rapid, the appearance is extremely beautiful.

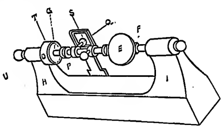

Fig. 59.

"The brush of light which appears on a point when presented at same distance from the conductor, is also by this means shown to be an intermittent action, notwithstanding its permanent appearance; its reflected images present, however, this remarkable peculiarity, they are elongated in the direction of the motion, proving that the brush is not so transient as a spark, and that the explosions which constitute it last during one interval of time measurable by the motion of the mirror.

"But this instrument is not confined to observe merely the intermittences of electric light; whenever a rapid succession of alternations occurs in an object which does not change its place, they may be separately examined by this means. Vibrating bodies afford many instances for investigation; one among them is perhaps worthy to be mentioned. A flame of hydrogen gas burning in the open air presents a continuous circle in the mirror; but while producing a sound within a glass tube, regular intermissions of intensity are observed, which present a chain-like appearance, and indicate alternate contractions and dilatations of the flame corresponding with the sonorous vibrations of the column of air."

To increase the chances of observation of sparks, etc., when their appearance cannot be commanded at the instant when the mirror is in the position to reflect them to the eye, Wheatstone proposes the use of a mirror formed of a hexagonal prism with polished faces, as shown in Fig. 60, where A B is the axis of rotation, and C, D, E, three of the reflecting facets.

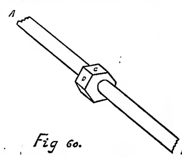

Fig 60.

With this mirror the observer will have six chances of seeing the reflected image instead of only one, as he has when using a rotating mirror with one polished surface.

On the Determination of the Velocity of Electricity through Conducting Bodies.—In the trials made to find out the velocity of electricity previous to Wheatstone's experiment, they used a long conductor, whose two ends were brought near each other so as to form a nearly closed circuit. One of these ends was placed at a short distance from a wire which went to earth, the other end was placed near a conductor leading to an electrical machine, or battery of jars. The experimenters had hoped to have seen an appreciable interval between the passage of the spark to one end of the conductor, and its appearance at the other end on its way across the space to the wire which led to the earth. In one experiment made near London in 1747, they used four miles of conductor, and the discharges at the two ends of the circuit appeared to be simultaneous to the experimenters; and naturally so, for if they had been separated by the 1-10th of a second the discharges would have appeared simultaneous by reason of the persistence of the sensation of light; and though they might have detected by the ear an interval of 1-10th of a second separating the sounds of the discharges, yet they would not have been able to detect an interval of silence between discharges separated by 1-100th of a second. It follows that in a circuit of four miles the detection of a velocity of only a few miles a second would be the limit to such methods of observation, even allowing that the method under any circumstances would give a result indicating an actual transfer of electricity from one end of the conductor to the other.

Wheatstone, after speaking of these trials, says, "I determined, therefore, to repeat a similar experiment, substituting for the imperfect judgment of the eye a revolving mirror, but more rapid in its motion and accurate in its indications than any I had previously employed. The instrument I am about to describe will, unless there be some error in the estimate, which I have not been able to perceive, measure beyond the millionths of a second; and this degree of minuteness may be yet far surpassed by more costly instruments and more careful observations."

It is often stated in text-books that Wheatstone's experiment on the velocity of electricity favors the hypothesis of two electric fluids. That this opinion should be so generally diffused is not a little remarkable, and when the reader has perused the following paragraph he will see that Wheatstone says distinctly that the expected result of his experiment is as readily explained by the hypothesis of one fluid as by that of two fluids. "But," speaking of the experiment of 1747, "as it is only on the hypothesis of an actual transfer of a fluid from one end of the wire to the other that a difference of time between the two sparks at its opposite extremities might be expected to be observed, in order to render the proposed experiment independent of this theoretical view, I took the necessary precaution of bringing a third spark, formed by disconnecting the middle of the wire near to and in a line with the extreme sparks. For on the supposition of the transfer of two fluids in opposite directions, the extreme sparks would be simultaneous, but the middle spark later in its occurrence; the same appearances would also accord with the theory of one electricity, if we admit that a disturbance of electric equilibrium is simultaneously propagated from each end, arising in the one case from successive additions to, and in the other from successive subtractions from, the neutral quantity in the conducting wire."

The experiment of Wheatstone's was made in the Adelaide Gallery of Practical Science, London, where our countryman, Saxton—who aided Wheatstone in these experiments—was then exhibiting his magneto-electric machine and other ingenious inventions. The total length of wire used was half a mile. This was stretched between the balustrades (A B and C D of Fig. 57) of the gallery in 20 parallel lengths, each 120 feet long. The ends of the wire marked 2, 3, 4, 5, of Fig. 57, were connected to the similarly numbered wires of the *spark board*, shown in Fig. 58. This spark board was fixed against the wall, so that the six balls (shown as circles in the figure) should be in a horizontal direction and parallel to the axis of the rotating mirror. The distance shot over by the sparks was 1-10th of an inch. The conducting wire was of copper and 1-15th inch in diameter.

Fig. 56 gives a general view of the apparatus to rotate the mirror and its electrical connections with the Leyden jar, M, and the conducting wire and spark board through the wires marked 1 and 2. Fig. 59 is an enlarged view of the mirror and the attachments thereto which Wheatstone used to obtain the spark at the right instant for observation, and to determine the number of revolutions made in a second by the axis of the rotating mirror. Similar parts in the two figures bear the same letters. The mirror, E, is of polished steel, one inch in diameter, and mounted on the shaft, F G, so that the plane of reflection of the mirror is in line with the axis of rotation of the shaft. The mirror was rotated by a cord going over the wheel, K L, and a groove in the axis, F G. This wheel, K L, was so large that, if the cord is supposed not to slip, the axis, F G, will make 1,800 revolutions to one of the wheel. M is a small Leyden jar, which is kept constantly charged with positive or negative electricity by means of the chain, N, connected with an electrical machine. From the inner coating of the jar leads a bent wire to the two insulated rods, O and P. The ball on the end of P is quite close to the knob, Q, on the axle, F G, when this knob comes opposite the ball on G in the rotation of this axle. In order to confine to narrow limits the spark which passes over this interval, Wheatstone placed between the knob, Q, and the ball on O a piece of mica, S, with a narrow horizontal slit in it. When the plane of the mirror is stationary and at 45° with the horizon he saw, on looking down vertically into it, the image of the balls on the spark board. Charging the jar, M, and rotating the mirror, the observer saw three sparks pass on the spark board and another pass from the knob, Q, through the slit in the mica to the ball on O. The path of the electricity may be supposed, for simplicity of explanation, to go from the outside surface of jar by the wire 1 to the wire 1 on the spark board; thence, with a spark to wire 2, and through half of the stretched parallel wires to 3; thence with a spark to wire 4; thence through the remaining half of the stretched wire to 5; thence with a spark to 6, and back to wire 6, attached to the standard of rotating apparatus and to the inner coating of the jar.

Without a knowledge of the exact number of revolutions made by the mirror in a second one cannot compute the value of deflections of the sparks in case they should be appreciable, and Wheatstone spent much time in the endeavor to get the exact velocity of the mirror. At first he used a siren, shown in Fig. 59, at T, attached to the axle, F G. With 800 revolutions to the axle, and leading air to the siren even through a few holes, the sound produced was so acute that it was either inaudible or its pitch was so high that the ears could not determine the note, and when the number of holes were reduced so as to lower the pitch the sound was too feeble to be distinctly heard. He then simply placed a small piece of paper so that the arm, P (which acts as a counterpoise to the arm and knob, Q), would strike it once at each revolution of the shaft of the mirror. When the mirror was now revolved with the maximum velocity the knob striking against the paper caused the sound G—4, which showed that the mirror was making 800 revolutions in one second of time. In subsequent experiments Wheatstone used a counter attached to the shaft of the mirror, and when thus retarded by this additional work put on it, the shaft made 600 revolutions per second.

Of the extraordinary powers of this apparatus as an instrument of research, and of the results of his experiments with it, Wheatstone speaks as follows: "Let us now consider what is the shortest duration of the electric light, and the greatest velocity of transmission through the wire, that can be detected by means of the instrument I have described. The mirror revolves 800 times in a second; and during this time the image of a stationary point would describe 1,600 circles; the elongation of a spark through half a degree, a quantity obviously visible, and equal to one inch seen at the distance of ten feet, would therefore indicate that it exists the 1-1,152,000th part of a second. The deviation of half a degree between the two extreme sparks, the wire being, as above stated, half a mile in length, would indicate a velocity of 576,000 miles in a second. This estimated velocity is on the supposition that the electricity passes from one end of the wire to the other; if, however, the two fluids in one theory, or the disturbances of equilibrium in the other, travel simultaneously from the two ends of the wire, the two external sparks (on the spark board) will keep their relative positions, the middle one will be alone deflected, and the velocity measured will be only one half that in the former case, viz., 288,000 miles in a second.

Repeated experiments gave the following results. In all cases, when the velocity of the mirror exceeded a certain limit, the three sparks were elongated into three parallel lines, and the lengths became greater as the velocity of the motion was increased. The greatest elongation observed was about 24°, indicating a duration of about the 1-24,000th of a second. The lines did not always commence at the same places; sometimes they appeared immediately below the eye, sometimes to the right, at other times to the left, and occasionally they were out of view altogether. This indetermination is owing to the arm, 2, of Fig. 58, not always taking the spark at the same distance from the discharger; several discharges are therefore required to be made before the eye can distinctly observe the appearances. When the velocity was low the terminating points (*i.e.*, the ends of the luminous lines of the elongated spark images) appeared in the same horizontal line; but when the velocity was considerable, and the upper edge of the mirror was revolving from the observer, the lines assumed this appearance ; when the top border of the mirror revolved toward the observer the lines appeared thus . In no case did I see them thus , or thus , as required in the actual transfer of a single fluid. The spark board in all these experiments was placed at the distance of ten feet from the mirror.

The interpretation of these appearances observed by Wheatstone in his mirror is as follows: First, the mirror in its revolution had time to turn 12°, while the spark lasted between the balls on the spark board, and as the mirror produces in the image double the angular deflection of its own motion, the spark appeared elongated over an arc of a circle equal to 24°. Since the mirror, by one revolution, spreads a reflected image out into two complete circles, or $2 \times 360° = 720°$, it follows that 800 turns per second of the mirror spreads out a reflected image into $800 \times 720°$, or 576,000°; and $\frac{576,000}{24} = 24,000$. Which gives 1-24,000th second for the duration of the spark on the spark board in Wheatstone's experiment.

The observer sees another peculiarity of these elongated sparks; they are parallel, but they do not have their origin on the same horizontal line. When the mirror in its motion is deflecting the spark image downwards, they present this appearance , which shows that the sparks at the beginning and the end of the wire, or circuit, took place at the same instant, and that a small interval elapsed before the spark made its appearance at the broken place in the middle of the wire, and that during this small interval which elapsed the mirror had time to get a slightly greater tilt than that which it had when the side sparks appeared, so the middle spark line appears as pushed *downward* between the two side spark lines. When the mirror revolves so that the images of the sparks are drawn out in an upward direction, then the middle spark line appears slid *upward*, between the two side lines, by the same quantity that it was slid downward by the same velocity and opposite direction of rotation of the mirror.

Wheatstone states that the amount of downward or upward displacement of the middle spark line amounted to not more than one half of a degree. Now, as an elongation of 24° in the spark line gave 1-24,000th of a second for their duration on the spark board, it follows that the displacement of half of a degree gives us 1-48 of 1-24,000th of a second, or 1-1,152,000th of a second, for the time it took the electricity to go over ¼th of a mile, or half of the entire length of the copper wire; hence in one second, electricity, according to Wheatstone's experiment, will travel over $\frac{1,152,000}{4}$, or 288,000 miles of copper wire.

The very large elongation of 24° in the sparks produced in the peculiar and unusual conditions of these experiments led Wheatstone to hope to be able to elongate sparks as they are ordinarily produced by the discharges of electrical machines or Leyden jars through short conductors of very slight resistance; but he observed no elongation in the sparks even when the mirror was urged to the greatest velocity of rotation. This shows that electric discharges taking place under the above conditions cannot have an existence as long as the 1-1,152,000th of a second; for if they had had a duration of that length then Wheatstone would have caused an appreciable elongation in them. Frequently we meet with the statement that Wheatstone showed that the discharge of a Leyden jar lasts the 1-24,000th of a second. We see that Wheatstone distinctly

34

Alarm Produced on the Discovery of the Leyden Jar.

In describing the effect produced on himself by taking the shock from a thin glass bowl, Muschenbroek stated in a letter to Reaumur, that "he felt himself struck in his arms, shoulders, and breast, so that he lost his breath, and was two days before he recovered from the effect of the blow, and the terror," adding, "he would not take a second shock for the kingdom of France." M. Allamond, on taking a shock, declared "that he lost the use of his breath for some minutes, and then felt so intense a pain along his right arm, that he feared permanent injury from it." Winkler stated that the first time he underwent the experiment, "he suffered great convulsions through his body; that it put his blood into agitation; that he feared an ardent fever, and was obliged to have recourse to cooling medicines." The lady of this professor took the shock twice, and was rendered so weak by it that she could hardly walk. The third time it gave her bleeding at the nose.

STATIC ELECTRICITY.

[16631.]—In reply to "Jay Aitch," [illegible], I do not think that I went at all too far in saying that as a matter of fact an isolated body is incapable of receiving an electric charge. It is quite true that this statement will not be recognised as a matter of fact by all electricians, but that is simply because perhaps the majority of electricians have so habituated themselves to looking at facts through the medium of old theories (set up before knowledge was sufficiently advanced) that they are unable to see what is really fact. Most of the electrical science of the day is due to mathematical analysis; and given any foundation of fact whatever, this analysis can be set up and a scheme devised to fit the supposed facts. Now the earliest observations in static electricity were directed to surfaces or bodies connected to the prime conductor of machines and themselves carefully insulated. Theories of electricity were based upon these observations, and the mathematical developments spring from them. Among other supposed analogies we have a number of problems about isolated bodies in infinite space, the charge upon them, and the work to be done in bringing other bodies near them; and of this class of ideas that of Prof. Ayrton as to the magnetism of the earth resulting from such a static charge upon the rotating earth is the latest.

But by degrees it became evident that the facts were only half facts, that the positive charge on the isolated body was always accompanied by a negative charge of equal quantity on surrounding bodies. To fit these new facts into the old theory (a work very like that of repairing old garments with new cloth) the theory of induction was created, that is to say, this negative charge was supposed to be a consequence of and produced by the positive charge, and to be itself subject to all the old laws of distribution.

Further progress showed us that so far from this being the case, the positive and negative charges are essentially one, indissolubly connected, so that the positive charge is incapable of existing at all except in presence of an equal negative charge connected to it by lines of force. As a consequence, inevitable but not yet recognised fully, charge is not seated upon or connected with the surfaces at all. These only make its presence manifest, serving the same purpose as the two plates of the decomposition cell. The charge itself (which, as I have lately shown, is simply energy [illegible] latent or potential), is located in the intermediate space, the dielectric; that is to say, all those actions which are classed as charge are simply instances of condensation; the isolated charged surface has no existence; it is simply a change of medium in a closed circuit. Therefore, before we can talk about the effect of a static charge on the surface of the earth, we must ascertain where the surrounding negative charge is. I have an intense dislike to propositions in which we are invited to assume conditions wholly out of range of experiment; we can by no possibility experiment upon a body isolated in space; but as we know that in no case can we put a charge upon an isolated body in earth, that as the more and more we approach those conditions, that is to say, the further we place our charged body from surrounding bodies, the more and more difficult it becomes to charge it, it seems to me mere absurdity to base any arguments upon that state of things existing beyond our means of experiment, which our experiments give us no reason to expect, but the occurrence of which they negative.

"Jay Aitch" will see therefore that the consequences he anticipates from the nebular hypothesis will not follow. Electricity is an essentially dual force. I do not mean any two-fluid stuff. I mean that it depends absolutely upon closed circuits of polarised molecules of matter in which energy can be transferred; the positive and negative are everywhere equally in that circuit; they are simply the opposite faces in every part of the chain or circuit. Open such a circuit anywhere, which means introduce a dielectric (as the air) into it, and you have the opposite static tensions. Electricity is known under no other conditions; deny it the circuit, and the energy which might appear as electricity becomes simply heat.

Sigma.

[36976.]—**Winter's Condensing Ring.**—Mahogany is generally used, but I have made one of pine. For a ring 18in. diameter, get two straight-grained pieces, 4ft. 6in. × 1¼in. × ¾in., plane true, put a groove down middle of flat side of each for the wire to lie in, steam them, and bend them to a circle. When dry and stiff put in the wire and peg them together, gluing the joint. Allow to dry thoroughly, round off, fix the ends on a wooden knob with pin to fit in top of conductor, smooth the whole well with glasspaper, and varnish with shellac. The wire should be brought out for connection with the prime conductor. There should be a collector for each surface of the plate. In Winter's machine these are of smooth varnished wood, ring shaped, having, in the side next the glass, a groove lined with tinfoil, in which the points are set.—J. Brown, Belfast.

[From the *Journal of the Society of Telegraph Engineers*.]

EXPERIMENTAL RESEARCHES INTO MEANS OF PREVENTING INDUCTION UPON LATERAL WIRES.

Journal of Telegraph Aug 1st 1879

BY PROF. D. E. HUGHES.

The induction upon lateral wires has of late years been a serious question upon telegraph lines—the constantly increasing number of wires upon the same poles, added to the adoption of high speed and consequent sensitive apparatus, renders the study of these effects of the first importance.

The disturbing effects have become each year more and more remarked; and in 1868, by the desire of the French Telegraph Administration, I undertook a series of practical experiments, with a view of finding a remedy. I at once perceived that we had to deal with a question of a more complicated nature than was at first supposed. We found then that we had to deal with the static charge of its own line, and the dynamic induction of the lateral wires, that the effects of each were very different; and whilst it was easy to deal with the comparative feeble static charge, the more powerful and rapid effects of dynamic induction could hardly be suppressed. By introducing extra resistance coils we could reduce the induced current, but, at the same time, we should reduce the current with which the line was working. The remedy was in most cases (particularly during faulty insulation) worse than the disease. Condensers and polarization batteries would allow the momentary induced currents to act, whilst it prevented the more prolonged currents of the distant station. Ordinary induction coils would allow of compensation if we had only two wires to compensate for; but as we had to consider ten or more wires they were useless for that purpose. The only remedy we then found was by the introduction of an electro-magnet, with an armature fixed upon its poles—thus being a closed magnetic condenser. This practically absorbed or destroyed all the short momentary currents; but then if on this line the apparatus was working at high speed, with consequent short currents, we practically cut off the best part of the current needed.

In this case, whilst the remedy was practically perfect for an apparatus at low speed with comparative long currents, it was useless for those working at high speed requiring shorter currents, and consequently more sensitive organs of reception.

Other duties prevented me at that date from following up this line of research. The disturbances on the lines from this cause have been on a constant increase from the adoption of more rapid, and consequently more sensitive, organs; and in the telephone we have at last arrived at an organ of rapidity and sensitiveness which not only reveals the constant induction, but which is the main reason why the telephone has not been more largely adopted upon telegraph lines.

In a late paper upon induction* I brought to notice the powerful organs of research in this field that we possess in the telephone and microphone; and we thought that by the aid of these we might investigate, theoretically, the cause and remedy for lateral voltaic induction.

The following experiments are a *résumé* of the results obtained:—

We made use of three separate and distinct means of research. The first consisted of two or more parallel wires, 20 feet long; the one being used as a primary, was connected to battery and microphone, with clock as source of sound (both ends of wire being to earth). The secondary wire, upon which the induced current was observed, was connected to telephone—both ends of this line also being to earth.

The second arrangement was made, in order to study the effects upon a much shorter length, and with more accuracy than could easily be obtained on the longer line.

Two parallel—1 millimetre, copper wires were strung upon a board, 15 × 15 inches; these wires were placed 10 inches apart, and both united at one end with 1 Daniell element placed near. The free ends of these wires could be put alternately in connection with battery; and thus, if we surrounded one of these wires with tin-foil, or other means of protecting wires, we could observe the degree of protection obtained, by comparing it with the unprotected wire. A difficulty was at once felt in obtaining sufficient induction upon a parallel wire of such a short length. We obviated this, however, by the construction of a flat rectangular coil of 100 turns, having 4 inches side exterior. Now, by placing either of the sides of this coil near the primary wire, we had 100 parallel insulated wires, of a few inches—the influence, therefore, was multiplied greatly; we had also in this coil, on the opposite side, 100 parallel layers running in a contrary direction, so the resultant strength of current was simply that due to the different distances; and it was in order to diminish this, as far as practicable, that we made the coil square. The sound obtained by this means was amply sufficient for all the researches needed.

The third means was that usually employed, namely, the use of coils either superposed or wound together in the same helix; by this means powerful effects could be easily obtained: and as the results were identical, and verified by the three systems, we will at once relate the experiments with coils.

I. If we construct two flat coils of 100 yards of No. 30 copper wire each, and join one as primary to battery and microphone, the second coil as secondary, joined to telephone alone, we find that by placing one of these coils near, or within a few inches distance from the other, we hear distinctly the sounds of the clock on the microphone. Our object now being to screen the secondary coil, so as to reduce the induced current, and consequently sound obtained on telephone, we joined both coils to the same earth plate, without effect. We then took a sheet of copper, 1 millimetre thick, 12 inches square, and placed it between the coils, without effect; joined both coils to this plate, as if it were an earth plate between the coils, but no perceptible reduction of the induced current was thus obtained. We then put 10 thin 1-32 inch iron plates, 18 inches square, between the coils, again joining them as earth, but still no perceptible reduction.

II. The two coils were surrounded with several layers of tin-foil, thus enclosing each separately in a continuous metallic sheath. This, however, had no effect, and sounds were quite as loud, even when the sheaths were joined to [illegible]. Placing both these metallic-covered coils in a vase of salt water, and all to earth, had not the slightest effect, even when the copper plate was also interposed between the coils. Theoretically, these two coils here represented a submarine cable; and as we shall see by some following experiments, neither the sea-water, nor even a metallic sheath or tube around each wire would entirely prevent dynamic induction; and this has been proved in practice, as, upon a trial of the telephone between Dover and Calais, a Morse message was clearly read by Mr. Bordeaux, simply by the induced current from another wire in the same cable.

III. A single coil was made, having four separate insulated wires all wound together in the same direction. We could thus join these coils at their free

* "Comptes rendus de l'Academie des Sciences," Paris, Dec. 30th, 1878, and 20th Jan., 1879.

ends, making several combinations, each giving very different results. We will call these separate coils Nos. 1, 2, 3, and 4—the microphone remaining on the primary, and telephone on the secondary. No. 1 joined to microphone, No. 4 to telephone—induction strong, and consequently sounds loud and clear. Nos. 1, 2, 3, to microphone, all same direction, No. 4 to telephone—no perceptible increase of sound by the increased quantity of surface; similar results when 1, 2 to microphone, and 3, 4 to telephone.

Thus by no combination of parallel wires can we hope to diminish induction; but if we join Nos. 1 and 2 to microphone, so that the current from 1 returns by 2, then we have a complete screen—no sound whatever being now heard on the secondary coil No. 4. The same effect takes place if we join 1, alone, to microphone, and 3 returning by 4 to telephone. Consequently, if a telegraph line or a telephone line had a return wire upon the same poles, and absolutely equidistant from the inducing wire, we should have perfect protection, from the fact that the primary would then induce parallel currents in both wires in the same direction, but contrary to itself and these parallel currents would, being of equal force, neutralize each other. The remedy here is complete, although it is true that it would introduce a double resistance, and the cost of a double wire cable would probably prevent its use. Leaving, however, the practical objections to its use aside, we shall see by some following experiments that the remedy as regards prevention is absolute.

IV. Taking this same 4-wire coil, and joining 1, 2, and 3 to microphone, so that current goes through 1, returns by 2, and back again by 3, we then hear on No. 4 only one half the induction that would be caused by either wire alone.

V. Using still the same 4-wire coil, and sending by 1 and returning by 2, no sounds are heard, as we have already shown, but if we short-circuit either 1 or 2 we at once hear strongly the sounds induced by the coil that is not short circuited, in this case without interrupting the flow of the current or breaking the communications. We have produced or annulled an induced current merely by cutting off its protecting contrary direction coil, and if the microphone instead of being placed in the direct primary circuit is placed between the junction of 1 and 2, and either coil, we hear the sounds not by any variation in the primary circuit, but simply by the more or less protective influence of the return wire.

VI. If instead of a return wire of the same length in this 4-wire coil we use a shorter wire in the same coil, it does not protect it, except for the same length as the protective wire; and if as return we use an exterior coil at some distance apart but of same length as the primary, it does not protect it at all; this is evident, as from theoretical considerations we know that the return wire must be equidistant, and should be of equal length and diameter.

VII. Knowing that a metallic envelope diminishes in a slight degree the induction—first, by the work done in inducing parallel currents in this wire, itself when on a closed circuit, and, secondly, by the consequent diminution of force after such work—we tried how the many similar closed coils, introduced between the primary and secondary, would reduce the amount of induction to one-quarter of its original amount. The primary and secondary being placed 6 inches apart, the introduction of one or two similar coils between them gave no perceptible reduction of force, and it required twelve such coils to reduce the induction to one-quarter of the original amount, and this reduction only took place if the interposed coils had closed circuits; the instant the circuits were opened there was no perceptible difference with or without the twelve interposed coils. From this we draw the conclusion that the only reduction takes place when work is done in interposed coils by being on a closed circuit, and that it would require a tube of metal to surround a conductor at least twelve times the amount of primary wire, in order to reduce its inductive effects to the one-quarter as above stated.

VIII. The results obtained with coils were now applied to two lateral wires in a straight line 20 feet long—the primary being insulated by gutta-percha, and covered externally with tin-foil several times. Here we had the exact conditions which have been more than once proposed as a remedy or prevention of induction for the use of telephone lines. This covering, however, was found to be no protection at all, the induction was equally as strong with exterior coating to earth or open—theoretically there should have been a slight, and, as we have already seen, *very* slight reduction, but the difference was not perceptible. The induction through this protective covering gave loud sounds on the telephone, but if we used the outer tin-foil covering instead of a return wire for primary, then no sounds at all were heard; in fact, it formed a perfect protection, as we have already seen, in the 4-wire coil.

IX. The short local wire of 15 inches, already spoken of as the "second arrangement," was now used. The primary wire was led through a glass tube 12 inches long, which had 10 coverings of tin-foil, all joined to earth. This arrangement proved, as above stated, of no avail; the current, however, being returned by the tin-foil covering proved a perfect protection. In addition to the 10 tin-foil coatings we added 20 coatings or cylinders of thin charcoal iron—making an exterior diameter of four inches, and a total thickness of metallic sheath of ¼-inch between primary and secondary wire. As but little reduction was perceptible, we placed a magnetic needle, suspended by a silk thread, at a distance of 4 inches from the primary, and measured the deflection by current. Without any protective coating it gave 3 degrees deflection, with glass tube and 10 tin-foils to earth 3 degrees, with the additional 20 iron cylinders about 2½ degrees, thus the magnetic lines of the voltaic current pass easily through non-magnetic and magnetic bodies, and as the dynamic induction is due to the *change* in this field of force, it is easy to see why the numerous metallic sheaths failed to arrest the inductive force.

(To be Concluded in next number.)

Expériences sur la machine de Holtz

Nous avons eu plusieurs fois l'occasion de faire allusion à la théorie nouvelle imaginée récemment à Tokio par MM. Ayrton et Perry pour expliquer l'origine du magnétisme terrestre.

Il n'est pas sans intérêt de résumer sommairement les observations, fort curieuses du reste, qui ont donné à ces deux habiles ménechmes de la physique l'idée d'émettre une hypothèse dont plusieurs savants éminents se sont préoccupés.

Ces messieurs, ayant eu dans leur laboratoire de Tokio une machine de Holtz, ont répété les expériences de M. Rowland qui montre qu'une charge d'électricité mise en mouvement produit la déviation d'une aiguille aimantée tout comme le ferait un simple courant voltaïque.

L'appareil mis en rotation était un disque d'ébonite à axe vertical tournant avec une vitesse de 61 tours par seconde, au-dessous d'une aiguille astatique d'une sensibilité parfaite.

Le disque d'ébonite était doré sur ses deux faces et il tournait entre deux plaques de verre horizontales dorées et mises en communication avec la terre.

L'aiguille était parfaitement immobile quand le disque d'ébonite n'était point mis en rotation, quoiqu'il fût électrisé; mais il suffisait de lui imprimer un mouvement circulaire pour produire une action sur l'aiguille aimantée. Cette action n'était autre que celle du magnétisme de rotation d'Arago.

M. Rowland s'en est parfaitement rendu compte, et il prétend être arrivé à distinguer nettement cet effet de celui qui est produit par la rotation du disque électrisé.

Les expériences furent suivies pendant des mois au laboratoire de physique de Berlin, mais l'action n'atteignait jamais une intensité assez notable pour être mise au-dessus de toute contestation possible. M. Helmholtz ne trouva ou ne chercha pas le moyen de la rendre plus grande.

Nous nous bornerons pour le moment à renvoyer le lecteur à ce que nous disons plus haut dans notre article sur l'astronomie électrique. On y verra que nous nous servons de l'expérience de M. Rowland pour expliquer l'action que les astres dont l'état électrique est évident, peuvent exercer non pas sur leur propre magnétisme, mais sur celui des corps célestes qui gravitent autour du soleil et sur celui du soleil lui-même.

Ce nouveau genre d'induction serait différent des effets électro-dynamiques provenant de leur mouvement et viendrait le compliquer dans certaines mesures qu'il resterait à définir.

MM. Ayrton et Perry, qui croient avoir été beaucoup plus timides, ont été en réalité beaucoup plus hardis, car ils se servent de cette expérience pour expliquer une action véritablement imaginaire de la terre sur elle-même, sous prétexte que le mouvement des molécules intérieures n'est pas le même que celui des molécules superficielles. Cette manière de raisonner est éminemment anti-philosophique.

THE ELECTRIC DISCHARGE THROUGH COLZA OIL.*

By A. Macfarlane, D. Sc., F. R. S. E.

The electrical properties of colza oil which I have examined are its dielectric strength and some phenomena which accompany the passage of the spark. By the dielectric strength of a substance I mean the ratio of the difference of potential required to pass a spark through air under the same conditions. The electrodes used were two parallel brass plates each four inches in diameter. When comparing the gases the standard distance of the plate chosen was 5 mm. In the case of liquids it is convenient to observe for a shorter distance, and reduce the result by the law which previous experiments of mine have established, namely, that in the case of the discharge between parallel plates through a liquid dielectric, the difference of potential required is proportional to the distance between the plates. (*Trans.* R. S. E., vol. xxix. p. 563). One set of observations gave the ratio for colza oil to be 2.7, another gave 2.5. Hence 2.6 may be taken. I have now obtained the following table of dielectric strengths for liquids (1 being unity).

Substance.	Dielectric Strength.
Paraffine oil	3.7
Oil of turpentine	4.0
Paraffine liquefied	2.4
Olive oil	3.5
Colza oil	2.6

The specific gravity of the colza oil is .91. The passage of the spark was accompanied by the formation of gas bubbles, but there was no deposition of solid particles. As the 4-inch plates were placed horizontally in the oil a bubble produced by the discharge was prevented from escaping by the upper plate. When the upper plate is again electrified such a bubble behaves in the following manner. If it is large enough it will extend itself somewhat like an hour-glass between the plates, but if it is smaller it takes the form of an acorn with a flat base, the base resting on one or other of the plates. When the upper plate is charged positively the bubble is repelled so as to place its base on the lower plate; when the electricity is changed to negative the bubble remains with its base on the upper plate. A reversal of the order of charging did not change the effect. After a few electrifications a sufficient number of solid particles collect to form a chain, and thus interfere with the phenomenon, the bubbles then being lengthened out in a remarkable manner, but never repelled to the lower plate. When the upper plate was charged negatively, gas bubbles appeared to me to rise from the lower plate, as if they had been formed there. To test this point further I took some sparks between two smaller disks placed vertically in the oil. The gas-bubbles were observed to rise up at the negative surface as if they had been formed at the positive surface, and had been repelled or carried straight across, and then rose up at the negative surface. When the spark was taken between two points bent at right angles to two rods dipping into the oil, the bubbles were observed to shoot out in the direction from the positively charged point, and to circulate round the earth-rod some time before rising to the surface. These phenomena indicate that the bubble is positively electrified.

series of projecting points, directed against the top of the revolving di-electric disc, but not actually touching the latter. A rectangular piece of vulcanite, shown better in Fig. 2, is attached to the same, but placed opposite the points on the other side of the disc. The metal rod, E, with points similar to the one described above, is fixed against the lower part of the disc, and a movable rod, F, is in connection with E. The conductor, F, can be joined to "Earth" by means of a brass chain. In order to be able to give a clear explanation of the working of this most interesting machine, I must put down first those elementary

[illegible] flective aperture of the large mirror or object-glass [illegible] his typical eyepiece, he would find by [illegible] that? Taking your correspondent's telescope, [illegible] that this spot would [illegible] we get

It is more difficult to give a clear explanation of the action of the second part of this apparatus. To facilitate a thorough understanding of the process, I give the annexed diagram. A represents the glass disc of the friction machine, whose upper portion, before passing the points is charged with + electricity; it acts through the di-electric disc, B, on the opposite conductor, E, which discharges − electricity on the

Eng Mechanic Oct 10 1879

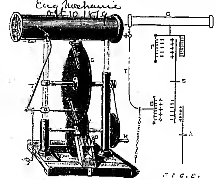

FIG. 1. FIG. 2.

scientific principles or laws upon which its action is based, and to which we shall have to refer.

After that I shall describe, separately, first the friction engine, and secondly, the induction apparatus.

1. Any substance which is not electrically excited is said to be at a neutral condition, and supposed to be charged with positive and negative electricity in the same degree; the two charges neutralising or destroying each other.
2. A body can be charged with positive electricity by having its negative charge abstracted, or *vice versâ*.
3. If a dry rod or plate of glass is rubbed with silk or leather, the glass becomes charged with positive electricity, the rubber acquiring at the same time a negative charge.
4. If the rubber employed in the process is covered with powdered amalgam, the result obtained is much better.
5. A plate of insulating material, say, glass or ebonite, placed between two bodies, of which one or both may be charged with electricity, is called a di-electric.
6. Electric induction by invisible agency takes place through the di-electric.
7. If a body charged with positive electricity (A, Fig 2) is placed near a dielectric, B, and a metal conductor E on the other side of the dielectric, the conductor E deposits negative electricity on the di-electric, and (according to principle 2 above) becomes charged with positive electricity.

1. The Friction Machine.

In the ordinary plate machine, as represented in the lower portion of our illustration, Fig. 1, a disc of glass, A, is made to revolve. Pressed against its sides are two cushions, D, to which a silk cover may be attached. The action of the apparatus is greatly improved if the cushions are covered with powdered amalgam, which is put on by means of tallow. The friction caused by the pressure of the rubbers against the plates excites the electric charge, in other words, it separates the two kinds of electricity, leaving a positive charge on the glass and a negative charge on the rubber. The amalgam naturally increases the friction and its results. (See principle 4.)

In such a friction machine, every portion of the disc, after having passed between the rubbers, approaches in its revolution a conductor with a series of sparge metal points directed against the glass. The charge of positive electricity on the glass abstracts the negative charge from the neutral conductor E, Fig. 1, and leaves the latter charged with positive electricity; while that portion of the disc which has just passed the points is charged with negative electricity. (See principle 2 above.)

If a di-electric is placed between the excited disc and the conductor, as shown in Fig. 1, the same action takes place, and (see principle 6 above) the di-electric and becomes itself charged with + electricity (see principles 6 and 2 above). But the di-electric in revolving carries the part that was thus charged with − electricity to the place opposite the top conductor F; it there abstracts + electricity from it F, becomes itself charged with − electricity (until it again passes opposite E), and leaves F charged with − electricity (see principle, Fig. 2). By means of a brass chain, shown in the illustration, Fig. 1, the conductor E can be connected to "Earth." If the disc A were charged with − electricity, then the same process would occur; but in that case T would be charged with − electricity, while F and C would acquire a positive charge. The machine has two more appendages, shown in the illustrations, of which we have not spoken yet. They are—(1) a rectangular piece of vulcanite fixed opposite, but parallel to F on the other side of the di-electric; and (2) the large metal conductor C. The slab of vulcanite increases the length of spark by one-third. The large metal conductor at the top fulfils a similar task. The brass-rod T is movable at its lower extremity, so that the brass ball fixed at the top of this rod can be placed at any desired distance from C to indicate any length of spark produced.

Some such machines are made with glass discs, others have plates of ebonite; both substances are equally effective and suitable for the purpose. A machine with a disc of 20in. diameter will produce a continued series of sparks, 5in. to 7in. in length; it is powerful enough to brilliantly illuminate several feet of Geissler's tubes, pierce glass, and produce all the effects that can be obtained from the secondary current of a large induction-coil. Carré's machines are made in three sizes having pairs of discs of the following diameters respectively, 12½in. and 17½in., 15in. and 21½in., 17½in. and 23½in.

Those of our readers who have occasion to experiment with friction machines, know that those are very sensitive to moisture in the atmosphere. The well known Holtz machine is even more sensitive than the former apparatus; but Carré's instrument is less susceptible to the evil effects of moisture in the air, and therefore recommends itself to the experimenter.

It possesses another and even greater advantage over the induction machines of Holtz and Hertsch in not requiring any initial charge from without, or necessitating any preparation. It is a self-starting machine. To set the apparatus to work, you simply turn the handle, and within one minute's time you hear the peculiar crackling noise which accompanies the long bluish sparks that pass between the conductors C and t. Our querist asks for "a few hints as to the best mode of keeping the apparatus in working order." 1. Keep the machine in a dry place; 2. do not allow the points of E and F to touch the disc; and 3, when needed put a little fresh amalgam on the rubbers. You will find that the instrument does not easily get

ELECTRODYNAMIC INDUCTION AND SECONDARY ELECTROSTATIC INDUCTION BETWEEN TELEGRAPH CONDUCTORS IN PROXIMITY.—In a Paper on this subject by M. de Meaux, in *Annales Télégraphiques*, the results of a series of experiments made (a) upon two gutta-percha covered wires, the external surfaces of which were insulated from earth, and (b) upon two such wires encased in lead by means of which the external surfaces of gutta-percha were connected to earth, are summed up as follows, so far as regards the electrodynamic effect:—*In a closed circuit, the intensity of the current determined by the induction of a cylindrical conductor of indefinite length upon another of the same form is not affected by surrounding one or other of these conductors, or even both of them, with a concentric metallic envelope, in communication with earth throughout its length.* In an article upon telephony, by Dr. Werner Siemens, in the same number of the *Annales*, the difference in the effects produced by the two modes of induction above mentioned is very clearly set forth. The following experiment, suggested by him, shows that the effects of secondary electrostatic induction are completely obviated by the external metallic envelope; the use of which, it appears, was patented in England by M. Foucault under date of 2nd July, 1869. Let *a*, *b* and *c* represent three sheets of metal foil, insulated from each other by plates of mica or thin layers of gutta-percha. When the plate *b* is disconnected

FIG 1 FIG. 2

from earth, the galvanometer *g* is reflected when the key *k* is depressed, by reason of the induction upon *c* of the charge communicated to *a*; this effect being in no wise diminished by the presence of *b*. If, however, *b* is connected to earth, then no effect is produced upon the galvanometer by depressing *k*; the induction being then exerted exclusively upon *b*. The analogy of this arrangement to the case of two conductors, enclosed in an insulating material which is coated externally with a conducting material, is shown in Fig. 2. When the conducting tube of A is connected to earth, the induced *minus* charge corresponding to the *plus* charge of the wire becomes accumulated upon the inner surface of this tube; whilst the *plus* inductions charge passes to earth. If, however, the conducting tubes of A and B were insulated from earth, they would both become polarised, and a *minus* charge would be induced in the central conductor of B; the *plus* inductions charge flowing through this conductor to earth. In regard to electrodynamic induction, Dr. Werner Siemens arrives at the same conclusion as that stated above; a conclusion established by the following simple experiment. Two gutta-percha covered wires are wound together upon a bobbin, which is gradually immersed in water. The effects of electrostatic induction are then observed to diminish; ceasing altogether when the bobbin is completely immersed. But the currents due to electrodynamic induction, instead of being diminished by the effect of the conductive contact between the external surfaces of the insulating coverings, which is established by the water, become by this cause intensified.

ON SOME POINTS CONNECTED WITH TERRESTRIAL MAGNETISM.

I HAVE on more than one previous occasion brought forward some of the various points which are here grouped together. These points are three in number.

(a) Regarding the sustaining power of the earth's magnetism.

(b) Regarding the diurnal and other changes of the same.

(c) Regarding earth currents and auroras.

I may state at once that this only professes to be a working hypothesis.

(a) *Regarding the Sustaining Power of the Earth's Magnetism.*—I do not here intend to discuss the cause of the earth's magnetism, but I would ask in the first place if it is not possible that this cause may be something small and one which (assuming it to continue at the present moment) we may not readily perceive. If we assume this cause or magnetic nucleus to be small is it not possible to imagine that there is a machinery which acts upon this nucleus (just as we have in certain magneto-electric engines) so as to swell up the magnetism of the earth ultimately to saturation.*

May not this machinery be the great convection currents, the anti-trades, that go from the equator to the poles in the upper regions of the earth's atmosphere, and which may be looked on as conductors moving across lines of magnetic force?

It would appear to me that the tendency of such currents will be to swell up and sustain the magnetism of the earth.

(b) *Regarding the Diurnal and other Changes of Terrestrial Magnetism.*—It will, of course, be natural, entertaining the views now enunciated, to regard the diurnal changes of the convection currents of the earth's atmosphere, as these are manifested in the upper regions, to be the cause of the diurnal changes of terrestrial magnetism.

If this view be taken it might be argued that wind changes in these upper regions should also produce magnetic variations. The reply is, that apparently they do. In conjunction with Mr. Morisabro Hiraoka I have compared together the simultaneous records of magnetic declination ranges at Kew and at Trevandrum, and I find evidence of a progress of things from west to east, so that on the whole a particular magnetic-range phenomenon occurs at Kew 9·7 days before it occurs at Trevandrum. Again, I have attempted to show, in conjunction with Mr. Dodgson, that a particular magnetic phenomenon occurs at Kew one day before it occurs at Prague.

It would thus appear that there is a progress of magnetic phenomena from west to east, just as we know there is a progress of meteorological phenomena. As, however, the meteorological phenomena which we can examine occur in the *lower* atmospheric regions, while the magnetic phenomena are, according to this hypothesis, associated with currents in the *higher* regions, it does not follow that magnetic and meteorological phenomena should travel from west to east at the same rate. I may also mention that we have reason to believe that magnetic changes lag behind corresponding solar changes just as meteorological changes would do.

It is manifest that it will be comparatively easy to settle the fact of a progress from west to east of magnetic weather, and that if such exists it will most readily ally itself with the hypothesis above mentioned.

In the next place, if we regard those changes in the convection currents of the earth which depend on the year, we have reason to imagine that such are most pronounced at the equinoxes. It is also well known that magnetic disturbances are most frequent at these times.

Let us next proceed to regard the secular change of the earth's magnetism. To account for this magneticians have felt the need of something movable, and the hypothesis of a "little earth," a solid nucleus moving within the recesses of our planet, has found much support. But is it not more likely that the result may be caused by a secular variation in the distribution of the convection-currents of the earth? If the question be asked, What reason have we for imagining the existence of such a variation, the answer will be, A much better reason than we have for entertaining the conception of a "little earth." For there is some reason, at any rate, for imagining the power of the sun to be subject to a complicated series of periodicities. Now a secular variation in the power of the sun would produce a secular change not only in the intensity, but in the direction of the convection currents of the earth, and, according to the above hypothesis, these in their turn would produce a secular magnetic change.

(c) *Regarding Earth Currents and Auroras.*—I have for some considerable time looked on the earth as a Ruhmkorff's coil with a magnetic nucleus. Above this nucleus we may suppose that we have the primary rocks, which are non-conductors, while above these we have the moist or comparatively moist surface of the earth, which is a conductor.

Above this, again, we have the lower strata of the atmosphere, which are non-conductors, while above this we have the upper strata, which are conductors.

Now suppose that a small but abrupt change of the earth's magnetism takes place, no matter how. We need not enter into the causes of such.

We have thus two secondary coils, if I may use the expression: (1) the moist surface of the earth ... regions of the atmosphere ...

* If I am not mistaken ... as a magneto-electric eng...

La Nature 31 Jan 1880

DESCRIPTION

DE LA PLUS GRANDE BOBINE D'INDUCTION

CONSTRUITE JUSQU'A CE JOUR

M. William Spottiswoode, Président de la Société Royale de Londres, a fait construire par M. Apps, fabricant d'instruments de physique à Londres, une bobine d'induction qui dépasse par ses dimensions et ses effets, tout ce qu'on avait réalisé antérieurement.

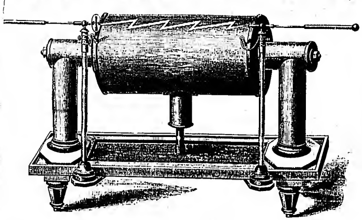
Nous en donnons la description d'après le *Philosophical Magazine*, sans presque rien changer au texte anglais de M. Spottiswoode.

L'aspect général de l'instrument est représenté par la figure ci-jointe. On voit que la bobine elle-même est portée par deux piliers massifs de bois, recouverts de gutta-percha et paraffinés à leurs deux extrémités. Outre ces deux supports, on en voit un troisième au milieu et dont la hauteur peut être réglée au moyen d'une vis, pour résister à la flexion de la pièce principale.

L'appareil entier est monté sur une base d'acajou portée par des pieds.

La bobine peut fonctionner avec deux circuits inducteurs qu'on utilise à tour de rôle. Deux personnes peuvent enlever l'un et lui substituer l'autre, en quelques minutes.

Le premier, qui sert aux longues étincelles et en réalité à la plupart des expériences, a un noyau



La plus grande bobine d'induction construite jusqu'à ce jour.

composé d'un faisceau de fils de fer de 8/10 de millimètre chacun, et formant ensemble un cylindre de 1m,11 de long et de 9 centimètres de diamètre. Il a un poids de plus de 30 kilog.

Le fil de cuivre qui constitue l'inducteur a une longueur de 600 mètres, un diamètre de 24 millimètres, une conductibilité de 95 centièmes, une résistance totale de 2,5 ohms., et un poids de 25 kilog. à peu près. Il est enroulé sur le faisceau de fils de fer, en 1344 spires disposées en 6 couches et se présente enfin sous la forme d'un cylindre de 1 mètre 6 centimètres, et d'un diamètre extérieur de 12 centimètres.

L'autre système inducteur, qui est destiné à fonctionner avec des piles de plus grande surface et à donner des étincelles courtes et nourries, pour des expériences de spectroscopie, a un noyau de fils de fer de 8/10 de millimètre comme les précédents, réunis ensemble et formant un cylindre de 1m,11 de long et de 97mm de diamètre. Le poids de ce noyau est de 41 kilog. Le fil de cuivre est le même que dans le premier circuit inducteur, mais le conducteur qui a 450 mètres de long est composé de 2 fils parallèles. Il est divisé en trois sections de chacune deux couches; leurs résistances sont respectivement 0,181, 0,211 et 0,231 ohms. La longueur du cylindre ainsi composé est de 1m,01 et son diamètre 14 centimètres. Le poids de ce fil est de 38 kilog.

Grâce à une disposition nouvelle, on peut disposer ces trois sections en une seule série, ce qui donne un conducteur de 4mm,87 de diamètres, ou en dérivation ce qui donne l'équivalent d'un conducteur unique de 14mm,65 de diamètre.

Ce fil inducteur a été employé pour fournir des étincelles de 86 centimètres de longueur (dans l'air

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 16.—"On Stratified Discharges. VI. Shadows of Striæ," by William Spottiswoode, P.R.S., and J. Fletcher Moulton, F.R.S.

One of the most interesting questions connected with the subject of stratified discharges is this: What is the physical, as distinguished from the electrical, nature of the striæ themselves? Are they, in fact, to be regarded as aggregations of matter possessing greater density than the gas present in the dark spaces, or are they to be considered as indicating merely special local electrical conditions? The fact of their having a definite configuration, especially on the side which is turned towards the negative terminal of the tube, that of their temperature being higher than that of the dark spaces, the manner in which they are affected by solid bodies, and other considerations, all tend to give support to the view that the striæ are loci of greater density than the dark spaces. Still it can hardly be said that as yet any experimental proof of this has been given sufficiently decisive to decide the question conclusively. And it is in the hope of contributing something towards the solution of this question that the following experiments are submitted to the notice of the Royal Society.

The two terminals of a Holtz machine were connected in the usual way with the two terminals of the tube, so as to produce a stratified discharge. A narrow strip of tin-foil, or a wire, was stretched along the tube opposite the column of striæ. The positive terminal of a second Holtz machine (in practice we used for this purpose a Töpler machine) was connected with the tin-foil, and the negative terminal with one (either) terminal of the tube. An air-spark, or interval across which sparks could pass, was interposed in the part of the circuit between the machine and the tin-foil. The effect of this arrangement was this: In the interval between two sparks the tin-foil and tube became charged like a Leyden jar; the tin-foil being the outer coating, charged positively, and the gas inside serving as the inner coating, charged negatively. When the spark passed across the interval mentioned above, the jar (*i.e.* the tube) became discharged, and the electricity previously held bound on the two coatings was set free.

When the first (say the "internal") machine was not working, or when it was disconnected, *i.e.*, when no regular discharge was passing through the tube, then, whenever a spark passed at the second (or "external") machine, a negative discharge with its accompanying Crookes' radiation took place from the inside of the tube next the tin-foil, and the opposite side of the tube became covered with a sheet of green phosphorescence (the tube being of German glass).

When, however, other things remaining as before, a discharge from the internal machine was sent through the tube, and a good stratified column was produced, it was found that the green phosphorescence was entirely cut off from the parts of the tube opposite to the striæ, while on the parts opposite to the dark spaces it remained, in the form of phosphorescent rings, as brilliant as before. The experiment was repeated with various tubes with various degrees of strength of current, and with various densities of gas (produced by heating a chamber of potash in connection with the tube). It may be added that when, as is sometimes the case, through greater exhaustion, the striæ became feebler in illumination and less compact in appearance, the shadows cast by them lost proportionally in sharpness of definition and in completeness of extinction of the phosphorescent light.

The brilliancy and definition of the phosphorescent rings may be increased by inserting a small Leyden jar in the circuit, care being taken that the jar shall discharge itself completely each time. If this is not the case the main discharge is followed by subsidiary discharges, which tend to blur the effect. The angle of dispersion may be increased, or rather supplemented, by placing more than one strip on the tube, distant from one another by an angle of 90° or 120°. By this means the rings may be made to comprise the entire circumference of the tube.

It thus appears that the striæ are competent to cast shadows in the radiant showers issuing from the inside of the tube adjacent to the tin-foil, which part acts as a negative terminal. Many experiments have contributed to show that these radiant showers, although accompaniments of the discharge, are not carriers of the discharge; and that, having once issued from their source, they continue their own course irrespective of that of the discharge proper. They are in fact material showers, and, although not improbably charged with electricity, yet their ulterior course does not appear to depend on their electrical condition. Under these circumstances the simplest explanation appears to be that they have been arrested by a material obstacle, and consequently the phenomena above described may be considered as furnishing an experimental proof that the striæ represent local aggregations of matter, and not merely special electrical conditions of the gas.

June 16.—"On Stratified Discharges. VII. Multiple Radiations from the Negative Terminal." By William Spottiswoode, P.R.S., and J. Fletcher Moulton, F.R.S.

On examining the image of a negative terminal as traced out in tubes of great exhaustion, by the phosphorescence due to Crookes' radiations, we have often noticed that the image was not a simple figure, but that more than one outline of the contour of the terminal might be traced. From the fact of the double contour having been first remarked when the terminal was of a conical form, it was at first supposed that the second image might be due to internal reflection, or to some property appertaining to the edge of the cone. But this supposition led to no satisfactory explanation of the phenomenon.

It was however thought that, inasmuch as the two images implied different systems of radiation, a magnet suitably disposed might affect them in different degrees, and thereby throw some light on their origin. For this purpose we used a large electro-magnet with its coils so coupled up as to give the two poles similar polarity. By bringing the two poles together, inclined at a moderate angle, a single pole and a field of great magnetic strength was produced.

The tube was then placed in the plane containing the axis of the two poles, and in the direction of a line bisecting their directions. The tubes first used were of great exhaustion, and were placed sometimes with the positive, sometimes with the negative terminal towards the magnet. When the tube was placed in a comparatively weak part of the field the two images of the cone were seen in their usual positions relatively to each other, except that they were slightly more separated. But as the tube was brought gradually into a stronger part of the field the two images became further separated, and by degrees a third, a fourth, and even more images were brought out on the side of the tube. In one tube of very high exhaustion, for which we are indebted to Mr. Crookes, as many as eight images became visible.

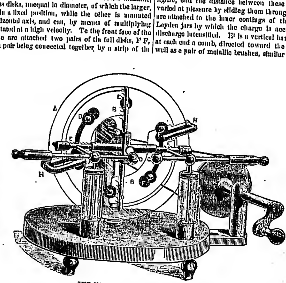
We have then, as an experimental fact, a series of images, each formed by a system of rays issuing from the surface of the negative terminal. The images being distinct, the system of rays must be distinct also. Now, as it seems hardly possible to imagine that, from every point of a surface, there can issue at one and the same instant of time a variety of systems of radiations, each system ranging over a finite angular distance, and each differently directed in space, we are driven to the conclusion that these radiations must have issued successively and not simultaneously from the terminal. In other words, the various images are formed in succession. Now, the entire series of images are present whenever a discharge passes through the tube; and when a "continuous" discharge (such as that from a Holtz machine) is passing, they are all as steady and as persistent as are any other features of the discharge. From this it follows that the radiations are not a continuous phenomenon, but that they are composed of a recurrent series of discharges, each having its own angular range, and its own direction in space; and as the electricity, which is the motive power, and the metallic terminal, which is the directing machinery, are the same in kind for each image, we are led to the conclusion that the positions of the images are determined by the force with which the radiations are projected. In fact, we understand that the various images are due to a succession of discrete discharges of successively diminishing strength.

The phenomenon of multiple images of the negative terminal as explained above has an important bearing on the nature of electrical discharges in vacuum tubes. For, if the phosphorising radiation consists of a recurring series of discrete discharges, the radiation in each series, and *à fortiori* the radiation as a whole, is discontinuous; and consequently the electrical discharge, to which it is due, must itself be discontinuous or "disruptive." We appear, therefore, in these phenomena to have an experimental proof, independent of and in addition to those adduced by Mr. De La Rue and others, of a fundamental point in the theory of these discharges, namely, their disruptive character.

42

VOSS'S INDUCTION ELECTRICAL MACHINE.

The modified Holtz machine, by Voss, possesses certain features rendering it of special value in this country, the most important of which is its independence of atmospheric conditions, assumed by the quartz. The following particulars and drawing are taken from *Engineering*. The machine, in the fact that it is self-charging, requiring neither friction nor any outside initial charge to start it into action, nor is it necessary to bring the discharge terminals into contact, as in the Holtz machine, before commencing to work it, is perhaps the best in existence. On reference to the illustration it will be seen that the apparatus consists, like the Holtz machine, of two glass disks, unequal in diameter, of which the larger, A, is held in a fixed position, while the other is mounted upon a horizontal axis, and can, by means of multiplying gear, be rotated at a high velocity. To the front face of the larger plate are attached two pairs of tin foil disks, F F, F¹ F¹, each pair being connected together by a strip of tin foil, and by a second strip to one of the two bent arms, H and H¹, by which they are connected to a light metallic brush directed toward the front face of the rotating plate. At the back of the fixed plate are pasted two paper coatings which correspond to what used to be called the paper "armatures" in the Holtz machine. To the face of the rotating plate are attached, at equal angular distances apart of 60°, and at a short distance from the circumference, six disks of tin foil (one of which is marked D in the figure), about an inch in diameter, corresponding in position and size with the tin foil disks upon the fixed plate, that is to say, if the disks, D, were numbered in rotation 1, 2, 3, 4, 5, and 6, those numbered 1 and 2 would, in a certain position of the rotating plate, correspond and be opposite to one connected pair of disks of the fixed plate; Nos. 4 and 5 would similarly correspond to the other pair, and Nos. 3 and 6 would have no disks on the fixed plate opposite to them. To each of the little tin foil disks, on the rotating plate and concentric with it, is attached a metallic button of the form of a plano-convex lens, and these buttons, in the revolution of the plate, pass under and are lightly touched by the metallic brushes, F F, which are held by the bent arms, H H¹, the brushes being so adjusted as only to touch the buttons and not to come in contact with the glass of the rotating plate to which they are attached. E' and E' are two horizontal collecting combs, insulated from one another by being attached to a horizontal bar of ebonite, but connected respectively to the two discharge terminals, O and G, in the front of the instrument by the horizontal bars shown in the figure, and the distance between these terminals can be varied at pleasure by sliding them through the balls which are attached to the inner coatings of the two cylindrical Leyden jars by which the charge is accumulated and the discharge intensified. E¹ is a vertical bar of brass carrying at each end a comb, directed toward the rotating plate, as well as a pair of metallic brushes, similar to F and F, and which also, in their turn, make momentary contact with the metallic buttons as they pass beneath them, and at a moment when they are not under the inductive influence of the metal disks of the fixed plate.



THE VOSS-HOLTZ ELECTRICAL MACHINE.

43

ON A NEW FORM OF MAGNETO-ELECTRIC EXPLODER

BY MARCEL DEPREZ.

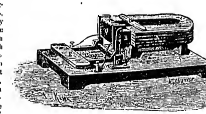
The different models of magneto exploders that have been invented during the last thirty years present the inconvenience of being of considerable weight and size and of giving very small sparks. On seeking to arrange an apparatus of such a nature for the purpose of inflaming gaseous mixtures in gas engines, I have reached results that are much superior to those given by the models already known, both as regards weight and the intensity of the spark obtained. A few very simple theoretical considerations led me to think that if, instead of utilizing, as done up to the present time, the current directly produced on the bobbins of an electro-magnet when the latter is suddenly withdrawn from its close contact with a magnet, the current thus produced should be sent into the conducting wire of a Ruhmkorff coil—the induced wire being employed to produce the spark—the results would be better. Such a modification of the mode of operation of the apparatus carries with it certain others in its construction and in the relative sizes of the parts composing it. As the current which traverses the inducting wire of the bobbin must have a pretty great intensity, the wire wound on the electro-magnet of the exploder must be coarse; and, besides, the breaking of the inducting current produced by withdrawing the electro-magnet must take place when such current (which leaves zero to return thither in a very short space of time) passes through its maximum intensity. It was on seeking to satisfy this last-mentioned condition that I was led to invent the new interrupter for induction coils that I have described on a previous occasion. Finally, I discovered that the electro-magnets employed in the ordinary exploders contained too great a quantity of iron, and that it would be of interest to make them much smaller. These preliminaries stated, I shall now pass on to a description of the two models that I have had constructed in order to apply the principles that I have just enunciated. The first possesses a magnet weighing 1·0 kilogrammes, and the second a magnet weighing about 8 kilogrammes.

In the first of these models, shown in Fig. 1, the armature of soft iron, B, is connected with a rectangular frame movable around the point, D. It is formed of a piece of soft iron plate bent at its extremities at B, in such a way as to fit *very accurately* against the magnet, A, whose poles have been dressed in a polishing machine. This armature is surrounded by a coarse wire (nearly 2 millimeters in diameter) connected by electric wires to the terminals of the apparatus, which are themselves put in communication with a Ruhmkorff coil of small size.*

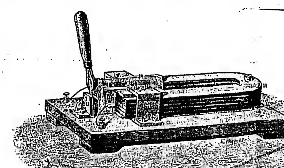
When it is desired to use the apparatus, a sharp blow is given to the small plate, E, and the screw of the interrupter of the induction coil is acted upon until the spark assumes a satisfactory aspect. With the small model there may be easily obtained a very hot spark of 3 millimeters in length, or a very brilliant one, destitute of an aureola, whose length may reach under favorable conditions at least 7 millimeters.

When the spring of the interrupter is given a feeble tension, two sparks may be obtained—the first at the moment of withdrawing, and the second when the armature is freely abandoned to the attraction of the pencil of magnetic rays. This latter may likewise be rendered very hot if its length be limited to about two millimeters. These two sparks develop a heat sufficiently great to set fire to a match moistened with naphtha, which is something that the sparks of the Holtz machine are incapable of doing, even when several hundred of them are directed against the moistened point.

Fig. 2 represents a more powerful model of a slightly different arrangement. The armature, A, is formed of a piece of soft iron plate 8 millimeters thick and 100 millimeters long, surrounded with a coarse wire, forming a bobbin, B. The whole is firmly joined to a brass frame movable around a horizontal axis which is in a line with the axis of the magnet, C D. The latter is provided at each extremity with two pieces of soft plate iron which are beveled off at the point at which the armature, A, rests against them. There are, then, always two of these pieces in close contact with A, and two others which are not, when the apparatus is at rest. If a smart blow be given the handle, F, so as to drive it, for example, from left to right, the magnetization of the plate, A, will not only be suddenly diminished, but even reversed, since it immediately abuts against the polar pieces of contrary name to those that it touched before the withdrawal. With this arrangement, then, more energetic effects ought to be obtained than with the preceding. Nevertheless, the apparatus that I have had constructed, although having an 8 kilogramme magnet, has not given effects that were proportionally as energetic as those afforded by the small model. I have not been able to cause it to produce sparks exceeding 10 millimeters, whatever was the size of the Ruhmkorff coil employed.—*La Lumière Electrique.*



NEW MAGNETIC EXPLODER.



NEW MAGNETIC EXPLODER.

A New Departure in Gunnery.

London papers state that the Superintendent of the Royal Gun Factories has adopted a new plan of increasing the initial velocity of projectiles. Having found by trial the description of slow-burning powder best adapted to his requirements, he has designed a contrivance for retaining the projectile in the chamber of the gun until the powder is sufficiently fired to set up a pressure of about two tons per square inch upon the base of the shot, which then starts at a bound, the speed of which is accelerated by the pursuit of the powder gases until it leaves the muzzle. The retention of the shot is accomplished by a ring of metal fixed around it near the base, and so regulated as to size that it will, when placed in the breech, be a trifle larger than the bore through which it has to pass. According to the resistance which it affords will be the period of retention. It has been demonstrated by experiments with fired gunpowder that in a very strong vessel the powder may be ignited and converted into gas, but yet held under subjection for an unlimited time. The retention ring is made of such strength that it will surrender at a given pressure, and the requisite conditions for the attainment of maximum velocities thus appear to have been realized. With the 10·4 inch gun a 402 pound shot has been fired at a muzzle velocity of 2,275 feet per second, the equivalent of which in energy is 10,500 foot tons, but as the powder charge was somewhat in excess of the service allowance it is fair to reduce this velocity by 100 feet. It will even then be far in advance of the speed attained under former conditions. The improvement has had a stronger illustration in a competitive trial between the two experimental 43 ton guns—that of Elswick manufacture, with the air-spaced chamber, and that of Woolwich, with the retention ring.

The former, with 350 pounds of powder (rather above its service charge), discharged a 700 pound projectile at a velocity of 1,900 feet per second; the latter, crammed with 400 pounds of powder and the same shot, recorded a speed of 2,120 feet. These figures represent in energy respectively 17,500 and 20,800 tons per foot, and the advantage in an attack upon armor plates may be assumed in the same proportion.

This improvement in gunnery, it is said, has created great satisfaction in the government departments, and great things are expected from it.

ABSTRACTS OF REPORTS, PAPERS, &c.

39 **Finding the Heights of Clouds.**

Mr. Francis Galton read a paper upon "Determining the Heights and Distances of Clouds." He said that this might be done by their reflection in a low pool of water and in a mercurial horizon. The calm surface of a sheet of water might be made to serve the purpose of a large mirror, in a gigantic vertical range-finder, whereby a sufficiently large parallax might be made for the effective measurement of clouds. The observation of the height and thickness of the different strata of clouds, and of the rates of movement, was at the present time perhaps the most promising, as it was the least explored branch of meteorology. As there were comparatively few places in England where the two conditions were found of a pool of water, well screened from wind, and of a station situated many feet in height above it, the author hoped, by the publication of this memoir, to induce some qualified persons, who had access to favourable stations, such as existed in Wales, to interest themselves in the subject, and to make observations. The necessary angles might be obtained with a sextant and mercurial horizon; but it would be convenient to have in addition a tripod stand, with a bar of wood across the top to support the mercurial trough, with some simple instrument for the rapid and rough measurement of altitudes.

NATURE Aug 26, 1880

A BALLOON ascent was made at Cherbourg, on the occasion of the *fête* given by the Municipality to M. Grévy, by MM. Perron and Capt. Gauthier. The general direction of the wind being from the land to the sea, a government steamer was sent out to secure the safety of the aëronauts if necessary. Before starting not less than thirty pilot-balloons were sent up to ascertain the superposition of the aërial currents. It was proved that at 400 metres the wind was blowing from the sea. After having travelled for more than an hour in the direction of Portsmouth, the aëronauts opened their valve and returned safely on shore. More than a hundred thousand spectators witnessed the experiment. The culminating point of the ascent was an altitude of 1,500 metres, where the travellers could see the English coast, the whole of the Isle of Wight, &c. The scenery is stated to have surpassed description. Some very curious observations were made on the colours of the sea. In the places where the water is very deep it looks quite inky, and the curves of level are so clearly manifested that they bear comparison with equidistant lines worked on ordnance maps. When travelling at so great an altitude ships can be detected with some difficulty; but smoke can be seen even when the smoke-producing steamer can hardly be perceived with the naked eye.

THE BALLOON SOCIETY OF GREAT BRITAIN.—At a meeting held on Friday at the Society's rooms, 5, Robert-street, Adelphi, W. H. Le Fevre in the chair, twenty-five new members were elected, amongst others, Colonel Sandeman, Commander Cheyne, F. Hilder, Carl Voigt, F.R.G.S., F. G. Capel, J. Gracie, and Professor Kalthaler. The President opened the meeting by referring to the recent balloon voyage out to sea at Cherbourg. Mr. Simmons stated that when he some years ago made a similar trip at Hull he went 20 miles out to sea, and then got into an anticipated return current which he found a few feet above the outward current, and which safely landed him at the desired spot on *terra firma*. The President observed that this interesting fact confirmed the opinion he had entertained for many years past that the currents travel only in thin layers, and move in every direction at different altitudes. He trusted the Society would eventually be the means of accurately and scientifically determining the laws by which these currents were regulated or influenced, and thus utilising them for the purposes of travelling as well as for meteorological objects. Captain Morton stated that he travelled on the 4th of August 37 miles in 18 minutes, and the President remarked that in all his calculations for large structures he never calculated on the wind travelling more than 80 miles per hour. The discussion was continued by Mr. Spencer and Mr. Simmons, who stated that from their own experience they could confirm Captain Morton's statement. The President read a letter from a member of the Society who had made one of his ascents in a thunderstorm, and found the atmosphere at an altitude of about 200 ft., and for a height of 100 ft. to be of a dull leaden hue, but as soon as he had risen above this stratum he found the sky quite unclouded, and witnessed perfectly clearly the storm raging below in all its grandeur. After a short discussion as to the best mode and means of inflating balloons in the Arctic regions, in which Commander Cheyne and others took part, Mr. Gordon, the honorary secretary, reported the arrangements that had been made for the balloon contest on the 4th of September next, and for which the following aeronauts had entered, viz., Mr. Wright, Mr. Simmons, Mr. Youens, Captain Morton, and Messrs. Side, Orton, Barker, Spencer, Adams, and Jackson. The [illegible] to be ascents to be made from the Crystal and Alexandra Palaces, the Lillie Bridge, Wormwood Scrubs, Epping Forest, Hendon, Kensal Green, and Clapham Rink.

Engineering Sept 10 1880

THE BALLOON SOCIETY OF GREAT BRITAIN.—At a meeting of the Executive Committee held at the office, 5, Robert-street, John-street, Adelphi, the President, W. H. Le Fevre, C.E., stated that the maximum distance travelled was 131 miles in 97 minutes, or at the rate of 26.907 miles per hour. A paper will be read before this Society by Mr. Simmonds, C.E., this evening, Friday, on "A New Form of Parakite."

Electrician Sept 9, 1880

39 Electrician Sept 9 1880

AT the last meeting of the Balloon Society of Great Britain the recent balloon voyage out to sea at Cherbourg was referred to. Mr. Simmons stated that when he some years ago made a similar trip at Hull he went twenty miles out to sea and then got into an anticipated return current which he found a few feet above the outward current, and which safely landed him at the desired spot on *terra firma*. The president read a letter from a member of the Society who had made one of his ascents in a thunderstorm and found the atmosphere at an altitude of about 200 feet and for a height of 100 feet to be of a dull leaden hue, but as soon as he had risen above this stratum he found the sky quite unclouded, and witnessed perfectly clearly the storm raging below in all its grandeur. On Saturday afternoon a balloon contest took place from various points in the neighbourhood of London, under the auspices of the Balloon Society. Eight balloons were to have started, but only five succeeded in getting away. A silver medal was to be awarded to the balloon that traversed the greatest distance in one hour and a half. The competition seems to have had some connection with Commander Cheyne's proposed Arctic Expedition; but so far as we have ascertained no new scientific results seems to have been obtained. One balloon seems to have attained a height of 14,000 feet.

DURING the Session of the City and Guilds of London Institute, commencing October 4, Prof. Armstrong, F.R.S., and Prof. Ayrton, Inst.C.E., will continue their tutorial and laboratory courses of instruction in Chemistry and Physics as applied to the Arts and Manufactures, at the Cowper Street Schools, Finsbury, in rooms rented from the Middle Class Schools Corporation, pending the erection of the City and Guilds Technical College, Finsbury. Dr. Armstrong will deliver a course of about thirty lectures on "Organic Chemistry, with special Reference to its Industrial Applications," on Mondays, at 8.30 to 9.30 p.m., commencing October 4. He will also deliver a course of about twenty-four lectures on Tuesday and Friday afternoons at 4 to 5 o'clock, commencing October 5. Although the chief object of these lectures is to afford such preliminary training as is necessary for those who may desire later on to study particular branches of Applied Chemistry, more than usual attention will be given to matters of technical importance. There will also be daily Laboratory Classes. Prof. Ayrton will deliver a course of evening lectures on "Electrical Instrument Making," on Tuesdays at 8.30 to 9.30 o'clock, commencing October 5, the first twelve of the lectures being given before Christmas. On Friday evenings, at 8.30 to 9.30 o'clock, commencing October 8, Prof. Ayrton will also deliver a course of lectures, the first twelve being given before Christmas, on "Weighing Appliances and Motor Machinery," adapted to the wants of makers and users of machinery. He will also deliver a course of about twenty-four lectures on Monday and Wednesday afternoons, at 4 to 5 o'clock, commencing October 4, on the "Electric Light."

MILITARY BALLOONING.

The Balloon Committee have been trying practical experiments as to how far it is safe for a "scouting" balloon to approach an enemy's lines, and the result of their inquiry has been most decisive upon this point. It is not so easy as it may at first sight appear to rise swiftly over the heads of friends and foes to a point of vantage whence every manœuvre may be watched with facility and safety. In the experiment which came off at Dungeness last week, one of the service balloons, such as would be employed for the ascent of one or two persons, was inflated and sent up, captive, to a height of about 800 feet, and at a distance of about 2000 yards from a battery furnished with one of the new 8-inch howitzers. The second shot was aimed and fired so deftly that it burst just in front of the balloon, a number of the fragments of the shell penetrating its envelope and lacerating it to such an extent as to bring it down in a very short time. The success of the experiment, in showing that scouts in the air cannot consider themselves safe when within the range of a field gun, was no doubt highly gratifying to the officers conducting it, but it will in no wise detract from the value of balloons for military purposes. 39

ON THE AURORA AND ZODIACAL LIGHT OF MAY 2, 1877.—Abstracted from a paper by Mr. Henry C. Lewis, at the American Association for the Advancement of Science. "A simultaneous appearance of an aurora and the zodiacal light appeared on this evening, and a comparison between them is here given. The various changes of the aurora are given in detail. A remarkable feature was the formation of a bright streamer which maintained its position relative to the earth for nearly an hour. Meanwhile, the zodiacal cone, which was bright early in the evening, had moved past the streamer and passed below the horizon. The streamer had remained, like the great pointer, fixed to the earth, and marking its motion, while the heavens revolved past it. This fact was conclusive evidence of the terrestrial character of the aurora and of the cosmical character of the zodiacal light. Another fact leading to the same conclusion was the character of their spectra. That of the zodiacal light was continuous, and that of the aurora was a line-spectrum—the former is such as would be given by sunlight reflected from matter in space; the latter would be given by an electric discharge through a gas." 39 Electrician Oct 9 1880

Electrician Oct 4 1881

ON A NEW METHOD OF AERIAL LOCOMOTION.

WITHOUT denying altogether the possibility of directing balloons, it must be admitted that all the great amount of human ingenuity applied for solving that problem has thus far given but very little practical result.

If we turn from this method of "floating" to that of "flying," by which the elevating as well as the propelling force had to be obtained by means of wings or propellers driven by manual or steam power, we will find that here too the result is hardly a positive one, as up to this day the weight of the motors applied has always been found to be too great in proportion to their motive force. Now, although it is very probable that in course of time this proportion of weight to power will greatly be altered in favor of the latter, still for the present no practical solution of that difficulty has been suggested.

But is there, besides the two already mentioned methods, no third one by which we could overcome the attraction of the earth?

Our answer is, Yes, there is a third method, based on a well known principle, which, however, up to this time has not been given due attention by inventors, and we may almost say by scientific men, as in several books on natural science and mechanics, I hardly found any allusion to the following phenomenon.

Let us suppose a hollow cylinder to contain gas under a high pressure; the moment we allow the gas to rush out one end, the cylinder will be pushed in the opposite direction by a force which will be proportional to the pressure of the gas and to the size of the opening. It is evident, however, that for the same cylinder we do not gain anything in effect by enlarging the opening, as by such a process we only augment the intensity of the force at the expense of its duration.

But if we succeeded in maintaining the inner pressure for a longer time without diminishing too much the size of the opening, we would obtain a continuously acting force which we might try as a motive power.

Now, the above condition can actually be realized for a certain length of time by filling the cylinder with a mixture of such solid bodies as, by being set fire to, will develop gases just as rapidly as these can flow out by the opening.

This is the way the motive force is obtained which drives the fire rocket with such astonishing velocity high into the air; and it is strange indeed that more attention has not yet been given to this kind of propulsive power, when the great number of failures already in the two over and over beaten tracks, ought to have forced aeronautical inventors to try in a new direction. Without entering too far into the failures that tried to frighten me out of these researches, I will relate briefly those only of the experiments that I think conclusive in this matter.

An iron tube 6 inches long by 1¼ interior diameter was fastened to a kind of suspended carriage, which by means of two wheels (one placed behind the other) could run easily on a wire stretched between two trees at the distance of 35 yards. One end of the tube was closed, the other had a thread for a screw cut over it, so that by means of a set of iron caps (having each one a different sized hole in its center) the opening could be reduced to 8, 6, 4, 3, 2, or 1 millimeter. The tube was filled with a composition as used for fire-rockets. First, no cap was screwed on, and the 150 grammes, taking about 14 seconds to burn out, had not been able to move the carriage weighing 2 kilogrammes. Next the 8 millimeter opening was employed. The result was only a total advance of about 6 yards by short, irregular jerks. The 6 millimeter cap had a far better result, as the carriage, beginning with a slow motion, traversed the entire distance in about 11 seconds, *i. e.*, before the charge was burnt out.

With the 4 millimeters the distance traversed at the end of the first second was over 1 meter, or very nearly equal to the effect produced by a well made fire rocket which burned about the same quality of powder per second; and the entire distance was run in seven seconds. With the 3 millimeter opening the carriage was, in less than five seconds, dashed with such force against the second tree that the wheels broke down. After remedying the accident, I expected from the 2 millimeter a much more brilliant success, but was entirely disappointed, as the carriage, although started with a high velocity, suddenly came to a standstill at the middle of the distance. On examining the tube I found the marks that gas had escaped between the tube and the cap, and as this escape took place in a direction contrary to that originally intended, it explained the standstill. This opinion was corroborated by lighting the 1 millimeter; as here the carriage, hardly it began to move, was hurled back again to the point of starting.

I intended (then in Paris) to continue these experiments, but previous engagements obliged me to leave for South America, where I could do nothing in this matter. Now, however, when after some years I again came to this country, where new ideas are not regarded with such distrust as in the Old World, I will try to take up again these researches, as it seems very probable that, besides the scientific interest, there can a practical result be reached, if this matter only be taken up with sufficient vigor. Now, in my former experiments the most of motive power obtained from 1 gramme composition was to impart to a mass of 75 grammes a velocity of 12 meters at the end of the first second; in other words, by burning 1 gramme of fuel per second we could overcome the weight of 75 grammes, and give that mass an additional velocity of over 2 meters at the end of the first second. But as the cylinders I was experimenting with could not have resisted more than 25 atmospheres, and as the velocity of gases issuing under 250 atmospheres must be considerably higher than the one that gave this result, it follows that the quantity of motive force obtained can be greatly augmented by employing cylinders of a greater resistance. To what limit the pressure, and consequent useful effect, can be brought advantageously, *this* must be the object of the next experiments, and this is the point which will decide whether this invention has to obtain a practical application or will only remain a scientific curiosity.

The objection that what we gained in effect by higher pressures we would have to lose by the necessarily greater weight of the more resisting cylinders: this objection only would hold good in case we imitated the construction of a fire rocket, where a cylinder capable of resisting the intended pressure holds all the fuel that is to be burnt during the entire traject.

The remedy is obvious. Far more serious objection to this kind of motors will be found in the price of the work, but I leave this question, as it would be impossible to discuss it before conclusive experiments shall not be made.

It is, however, to be supposed that even by an extremely high price it would find several applications, being able to fulfill several conditions not otherwise to be realized, among whom not the least curious is the circumstance that such a motor could do work even if placed above the atmosphere.

CHARLES SARKADY.

New York, November 1880

13

14

fact, but as the South American contrivance does not appear to have been witnessed by "H. A." himself, he will, perhaps, not feel hurt if I say that if the floating kite in some degree resembled the account he gives of it, yet we may be sure that some important matter of fact must have been overlooked in the description. My incredulity arises from the following considerations:—

(1) The kite, so soon as liberated, being wholly immersed in the current of wind, would go to leeward as fast as the wind, and there would, therefore, be no air pressing against its sloping surface to maintain it.

(2) The streamers from the same cause would be inoperative.

"Fiddler" (17819) quotes me (17806) "Vibration is not the motive power." The words I used are, "Vibration *in the cases mentioned by 'Fiddler,'*" &c., my allusion of course being to the facts mentioned in his letter (17752); and the case to which he now applies my remark is not (in the way in which he uses it) analogous. Vibration is, undoubtedly, as its very definition implies, a form of motion, and, as such, is a motive power. As matter is indestructible, so motion is continuous. Motion does not *make* heat; heat *is* motion, and the amount of work retained in a heated body is the momentum of the moving molecules; that is to say, it is a function of their *mass* and *velocity*. Light and sound also are motion, and so, no doubt, is electricity. There is no difference of the kind "Fiddler" supposes between light and heat. One is neither more attractive nor more diffusive than the other.

The only difference is that the movements (heat) which, while they fail to excite our eyes, are yet perceived as warmth by the nerves of the skin, are slower, and generally more ponderous, than those which we perceive as light. They contain more motion, and therefore yield more to the radiometer. "Fiddler" is wrong in supposing that the electric light has no action on the vanes. The vanes are moved by the molecules of air remaining in the so-called vacuum, not by the heat itself. When the vacuum is more nearly perfect, the motion lessens and finally ceases. I cannot conceive why he calls heat "fixed vibrations," and light "free vibrations." There is no such difference whatever. The burning glass concentrates both light and heat. Growing plants do not repulse light. The "electrical action when in the dispensing mode" is quite beyond my powers of comprehension. I try not to laugh at "Fiddler."

In the pretty experiment he describes, the sides of the tumbler move out and in at regular intervals. The intervals are small, because the tumbler is small; but nevertheless they shake, or move, the split match backwards and forwards, and that causes the mill to turn round, just in the same way as "Fiddler" might twirl a hooked stick round by a backward and forward movement of the hand. Electricity must be looked upon as motion of some kind. With it, though "Fiddler" says we can't, we can get power without fire or boiler, as in electro-motive machines.

"Mockershaeta" (17850) appeared desirous of understanding the undulatory theory. Of course, I don't pretend to the least particle of originality, and he would do best to read Helmholtz's "Familiar Lectures," where he will be learning from "one who knew."

If two series of ring-shaped waves are formed upon the surface of a placid pond they proceed to the edges of the pond practically unaltered in their shape, period, and energy from what they would be if either were formed alone. And yet they interfere, the one with the other, at the points of their intersection. Where crest crosses crest a pile higher than either wave is formed. Trough crossing trough produces a pit deeper than either trough. Crest crossing trough produces level. Look at the surface of a bay or estuary during a breeze. There roll the remains of the great sea waves formed away in the ocean by the accumulation of petty waves superimposed one on another. Their line in consequence of the retarding influence of long-shore friction tends to become parallel to the general coast line, and they therefore roll in at the bay's mouth, stretching almost straight across. Now, the bay itself being a miniature ocean, has its ripples, its wavelets, and its billows. These, in their due places, starting from the sheltered side in the order named, roll superimposed upon, or crossing the others, and where they have attained a sufficient size to be easily distinguishable, and where, also, the direction of the wind sends them across the greater sea-waves, they serrate their concentrated to their point of origin in the centre of the pond. Meeting the new waves constantly radiating at the same speed, the surprising phenomenon of stationary waves will be observed. I must not, however, attempt to use any more illustrations.

"Mockershaeta" states that the "rays" (or, as he ought to have said, "waves") [of light] "never interfere." In this he is of course completely wrong. The phenomena of interference may be said to be one of the most important supports of the undulatory theory. What would "Mockershaeta's" surprise be to learn that the phenomena of diffraction must be taken to establish the fact that not only is there interference, but that every point on the surface of every advancing wave of light must form a new centre from which spherical waves are originated. For the solution of this and the other points upon which he is "mixed up," I must respectfully refer him to a treatise on optics.

To revert to water-waves. As we stand on a gradually sloping shore watching the waves roll in, we find that there are maximum waves which roll much farther than others. These are the crests of very much larger waves upon which the others are superimposed.

Wetherby, 17 Sept. Sevverg.

FLIGHT OF BIRDS—"FIDDLER" ON VIBRATIONS—PHYSICAL HYPOTHESES.

[17903.]—In letter 17817, p. 33, F. H. Wenham, though, to my thinking, right in his views that the swiftly advancing plane will not descend so rapidly as the passive, has yet fallen into a slight error in introducing the very fascinating theory that the *weight* of the air passed over is effective in supporting the plane, because a flying machine at a greater height above the ground would pass over a greater quantity of air than at a lower elevation. He also appears to consider that the problem is directly in the proportion of weights, in the same way as a lever or a system of pulleys is equilibrated. Now the efficient factor is the inertia of the air. Of course inertia is proportional to mass, or weight; but what has to be determined is, what depth of air ought to be taken into account. An illustration of the effective inertia of a fluid occurs to me. The still surface of a sheet of water may be struck so smartly by the hand as to produce a sharp tingling, and those jumping into water are aware how frequently the inexperienced receive stinging blows from the violent percussion of the flatter part of the body, the abdomen, back, or even the head against the previously unmoving surface of the water. The way exception was taken some time back to the expression (quoted from the Duke of Argyll's "Reign of Law") "momentum of a motionless body." No doubt it is paradoxical, but not wholly meaningless. "Inertia" would ...

FLIGHT OF BIRDS.

[17935.]—Some years ago, in Ceylon, a brother planter and myself were out with our guns. Seeing a very large hawk, or eagle, flying over our heads, my companion fired, hit him and brought him tumbling to the ground nearly at our feet. On approaching him we found that, although severely wounded, he was far from being mortally hurt. His ugly beak, formidable claws, and menacing eyes, warned us that danger lurked in treating him with too much familiarity. The utmost we ventured to do, though he lay perfectly still, was each to take hold of the tips of his wings in order to stretch them out between us to their utmost extent, to judge of his size, and to admire their enormous spread. We, then, in mere wantonness, swung him backwards and forwards several times between us, and finally launched him forward with all our strength as far as we could throw him. Imagine our surprise to see him sail majestically away without the slightest visible motion of his wings, or change from the outstretched spread which our coupling had given them, to the hillside the other side of the valley. We stood near the top of a ridge of hills sloping to a deep and wide valley. The direction of his flight was downward, along a slightly-inclined plane.

R. W. I.

[17936.]—I shall confine my notice of Mr. Wenham's letter to the machines proposed by him, page 38 and 62.

First, as regards the former, I am surprised to find that I have been "egotistic, and risking my assumed authority," in supposing that the laths were placed at this distance. I did not intend to imply that a distance of that amount was required by the machine; but I really supposed that was Mr. Wenham's own idea, although, by omission, not explicitly stated. My reason for this was, that then all the air met by the machine would be opposed by some portion of aëroplane. It was not in consequence of any estimate of the forward resistance.

This resistance is stated by Mr. Wenham to be unknown to him; but then he has ascertained, I presume, the vertical resistance to be precisely 300lb. For "this angle or rise, represented as 1 in 63, will be that required to be given to the aëroplanes to maintain the equilibrium and the *level flight*, and sustain the weight of 300lb. So that the vertical resistance must be 300lb. Further, the resistance to a plane constantly kept at the same angle in line of motion, and moving horizontally with a given velocity, must be the same as if it moved vertically with the same velocity and angle. Now, when a plane descends vertically, the resistance has been supposed by Mr. Wenham to be that given by Smeaton, which would be, therefore, one would suppose, at all events, an approximate working hypothesis for the horizontal or forward resistance. But this is of comparatively little moment, only making the arrangement, to my comprehension, a shade more ascertainable. The important point is the assumption of one minute. That "actuating weights may be represented by an angle composed of the two forces" may be true, but I have not the least idea of the meaning. But that "actuating weights may be considered, irrespective of any given time," I think I agree with. I suppose it would include the assertion that when weights are in equilibrium they are in equilibrium always. But unfortunately Mr. Wenham's conclusion entirely depends upon the assumption of one minute. He says 300lb. is the 63rd part of 8·5 tons, which passes through the machine in one minute, and that therefore the rise to be 1 in 63 to support 300lb. But if the time is of no consequence, take one second as an "illustration" merely; then the quantity of air would be one-sixtieth part of 8·5 tons, and the rise by the same reasoning would be 1 in 3,600. Or, if we take one hour, the quantity of air would be 60 times 8·5 tons, and the rise would be 1 in 1; that is, the plane would have to be vertical, and if more than one hour, the reasoning would not apply at all. Further, if the forward resistance is unknown, how did Mr. Wenham know, except from his "inner consciousness," that the aëroplane required might be so many times too large to be included in the space of 72 square feet, being 18 inches wide.

The arrangement given, page 62, is liable to similar objections in an intensified form. There is no question as to the theory of the rotated arms, in which category falls the theory of wing-flapping whether the wings be stationary or in motion, paddle-wheels, and screws in motion. But upon further reflection with regard to a descending horizontal plane with horizontal velocity, if the velocity were not supposed to vary, and if the path were not curvilinear, the resistance would be the same as if the body descended vertically with the velocity of the body in its path, and with the plane at the same angle to the line of motion, and the streamlines would be steady. The resistance being ordinary, of course, when the plane and line of motion is absolutely horizontal, the pressure above and below is exactly equal, being the hydrostatic, and the resistance is absolutely nil, even if the velocity were a million miles per hour.

There are many things in Mr. Wenham's letter, page 87, that I could take exception to; but I will confine myself to one statement, page 88, third column.

A body weighing 21lb. and descending with a velocity (supposed terminal in air) of 1,320ft. would expend upon the air nearly ·81 H.P., that is 27,000 ft.-lb. per minute. But then, as a corollary it is stated that the same H.P., or, indeed, more is required to raise the body upon a yielding support like air. No height is here mentioned, but surely the ascent of a mile requires a larger total expenditure than an ascent of an inch. At the risk of making an exhibition of "egotism," I suppose an ascent of 1320ft. per minute is intended. Now, there is no necessary connection between the energy wasted upon the air during a descent of 1320ft. and the H.P. required to lift the bird the same height. In H.P. the idea of time is involved. To lift the bird 1,320ft. by action upon the air would certainly require an expenditure of more than 27,000ft.-lb. Let us suppose to fix the idea that 51,000ft.-lb. was required. But if one hour was occupied in the ascent the bird need not have more than 1-60th of a H.P. to accomplish the ascent.

I do not know whether the definitions of inertia given by "Sevverg," page 80, are familiar to any of your readers. They are new to me. One is "that inertia is proportional to the weight of the body into its velocity, and has the same value as momentum." Consequently, the inertia of a body not in motion is zero—that is, has no inertia, which shows clearly that inertia is not an essential property of matter. Again, momentum implicitly defined above as proportional to weight into velocity would be different for the same body and velocity at different distances from the earth's surface, which I was before unaware of.

I am not sure whether the idea is also intended, apparently in opposition to the previous definition, that a body at rest, but impinged upon by another body, has really inertia proportional to its own weight into the velocity of the other body. At all events, we have the information that if two bodies impinge upon one another, one being at rest and the other having velocity, the "force" is the same whichever body has the velocity. By force is, I presume, meant energy expended. That is to say, it makes no difference to me whether I fall on a mountain with a velocity of say 20ft. per second, or whether the mountain falls upon me with the same velocity. This is another novelty.

Page 80, third column, the same gentleman has made another discovery, which might perhaps be appropriately termed the atomic theory of time. It appears that "a period of time (that is, a portion of time) really consists of small portions of time." To say that a portion of time really consists of portions of time, is a very little more than saying that time consists of time, or at all events, that time may be conceived as divisible, which will scarcely be considered as information so valuable as to deserve any particular pointing out. But it is the word "small" which is the pivot which implies that no large portions are possible, otherwise, why say small? The word "large" would be quite as appropriate. This discovery may be expected to throw a flood of light upon the constitution of time, and merits special recognition.

"For the future, I will no longer stand in Mr. Wenham's way in matters connected with aërial navigation, for this will be my last utterance upon that subject.

W. O. E.

AERIAL FLIGHT.

(*Continued from page 80.*)

[17937.]—Experiments have been made to test resisting the power of conical bodies of various forms in the following manner:—A thin lath was placed horizontally, so as to move freely on a pivot set midway; at one end of the lath a circular card was attached, at the other end a sliding clip traversed, for holding paper cones, having their bases the exact size of the opposite disc. The instrument acted like a steelyard; and when held against the wind, the paper cones were adjusted at different distances from the centre, according to their forms and angles, in order to balance the resistance of the air against the opposing flat surface. The resistance was found to be diminished nearly in the ratio that the height of the cone exceeded the diameter of its base.

It might be expected that the pull of the string of a flying kite should give some indication of the force of inclined surfaces acting against a current of air; but no correct data can be obtained in this way. The incline of the kite is far greater than ever appears in the case of the advancing wing-surface of a bird. The tail is purposely made to give steadiness by a strong pull backwards from the action of the wind, which also exerts considerable force on the suspended cord, which for more than half its length hangs nearly perpendicularly. But the kite, as a means of obtaining unlimited lifting and tractive power, in certain cases where it might be usefully applied, seems to have been somewhat neglected. For its power of raising weights, the following quotation is taken from vol. xli. of the *Transactions of the Society of Arts*, relating to Captain Dansey's mode of communicating with a lee shore. The kite was made of a sheet of holland exactly 9ft. square, extended by two spars placed diagonally, and as stretched spread a surface of 55 square feet. "The kite, in a strong breeze, extended 1,500 yards of line five-eighths in circumference, and would have extended more had it been at hand. It also extended 360 yards of line, 1½in. in circumference, weighing 60lb. The holland weighed 3½lb.; the spars, one of which was armed at the head with iron spikes, for the purpose of mooring it, 6¾lb.; and the tail was five times its length, composed of 8lb. of rope and 14 of elm plank, weighing together 22lb."

We have here the remarkable fact of 92¼lb. carried by a surface of only 55 square feet.

As all such experiments bear a very close relation to the subject of this paper, it may be suggested that a form of kite should be employed for reconnoitering and exploring purposes, in lieu of balloons held by ropes. These would be torn to pieces in the very breeze that would render a kite most serviceable and safe. In the arrangement there should be a smaller and upper kite, capable of sustaining the weight of the apparatus. The lower kite should be as nearly as practicable in the form of a circular flat plane, distended with ribs, with a car attached beneath like a parachute. Four guy-ropes leading to the car would be required for altering the angle of the plane—vertically with respect to the horizon, and laterally relative to the direction of the wind. By these means the observer could regulate his altitude so as to command a view of a country, in a radius of at least twenty miles; he could veer to a great extent from side to side, from the wind's course, or lower himself gently, with the choice of a suitable spot for descent. Should the cord break, or the wind fall, the kite would, in either case, act as a parachute, and as such might be purposely detached from the card, which then being sustained from the upper kite, could be easily recovered. The direction of descent could be commanded by the guy-ropes, these being hauled taut in the required direction for landing.

The author has good reasons for believing that there would be less risk associated with the employment of this apparatus than the reconnoitring balloons that have now frequently been made use of in warfare. The practical application of these suggestions appears to have been anticipated some years previously. In a small work, styled the "History of Charvolant, or Kite Carriage," published by Longman and Co., appears the following remark:—"These buoyant sails, possessing immense powers, will, as we have before remarked, serve for floating observatories. . . . Elevated in the air, a single sentinel, with a perspective, could watch and report the advance of the most powerful forces, while yet at a great distance. He could mark their line of march, the composition of their force, and their general strength, long before he could be seen by the enemy." Again, at page 53, we have an account of ascents actually made, as follows:—"Nor was less progress made in the experimental department, when large weights were required to be raised or transposed. While on the subject, we must not omit to observe that the first person who soared aloft in the air by this invention was a lady, whose courage would not be denied this test its strength. An arm-chair was brought on the ground, then lowering the cordage of the kite by slackening the lower brace, the chair was firmly lashed to the main-line, and the lady took her seat. The main-brace being hauled taut, the huge buoyant sail rose aloft with its fair burden, continuing to ascend to the height of 100 yards. On descending, she expressed herself much pleased with the easy motion of the kite, and the delightful prospect she had enjoyed. Soon after this, another experiment of a similar nature took place, when the inventor's son successfully carried out a design not less safe than bold; that of scaling, by this powerful aërial machine, the brow of a cliff 200ft. in perpendicular height. Here, after safely landing, he again took his seat in a chair expressly prepared for the purpose, and, detaching the swivel-line, which kept it at its elevation, glided gently down the cordage to the hand of the director. The buoyant sail employed on this occasion was thirty feet in height, with a proportionate spread of canvas. The rise of the machine was most majestic, and nothing could surpass the steadiness with which it was manœuvred; the certainty with which it answered the action of the braces, and the ease with which its power was lessened or increased. . . . Subsequently to this, an experiment of a very bold and novel character was made upon an extensive down, where a wagon with a considerable load was drawn along, while this huge machine, at the same time, carried an observer aloft in the air, realising almost the romance of flying."

It may be remarked that the brace-lines here referred to were conveyed down the main-line and managed below; but it is evident that the same lines could be managed with equal facility by the person seated in the car above; and if the main-line were attached to a water-drag instead of a wheeled car, the adventurer could cross rivers, lakes, or bays, with considerable latitude for steering and selecting the point of landing, by hauling on the port or starboard brace-lines as required. And from the uniformity of the resistance offered by the water-drag, this experiment could not be attended with any greater amount of risk than a land flight by the same means.

The wings of all flying creatures, whether of birds, bats, butterflies, or other insects, have this one peculiarity of structure in common. The front, or leading edge, is rendered rigid by bone, cartilage, or a thickening of the membrane; and, in most birds of perfect flight, even the individual feathers are formed upon the same condition. In consequence of this, when the wing is waved in air, it gives a persistent force in one direction, caused by the elastic reaction of the following portion of the edge. The fins and tails of fishes act upon the same principle. In the most rapid swimmers these organs are termed "lobated and pointed." The tail extends out very wide transversely to the body, so that a powerful impulse is obtained against a wide stratum of water, on the condition before explained. This action is imitated in Macintosh's screw-propeller, the blade of which is made of thin steel, so as to be elastic. While the vessel is stationary, the blades are in a line with the keel, but during rotation they bend on one side, more or less, according to the speed and degree of propulsion required, and are thus self-compensating; and could practical difficulties be overcome, would prove to be a form of propeller perfect in theory.

In the flying mechanism of beetles there is a difference of arrangement. When the elytra, or wing-cases, are opened, they are checked by a stop, which sets them at a fixed angle. It is probable that these serve as "aeroplanes," for carrying the weight of the insect, while the delicate membrane that folds beneath acts more as a propelling than a supporting organ. A beetle cannot fly with the elytra removed.

The wing of a bird, or bat, is both a supporting and propelling organ, and flight is performed in a rapid course, as follows:—During the down-stroke it can be easily imagined how the bird is sustained; but in the up-stroke, the weight is also equally well supported, for in raising the wing, it is slightly inclined upwards against the rapidly passing air, and as this angle is somewhat in excess of the motion due to the raising of the wing, the bird is sustained as much during the up as the down-stroke—in fact, though the wing may be rising, the bird is still pressing against the air with a force equal to the weight of its body. The faculty of turning up the wing may be easily seen when a large bird alights; for after gliding down its aërial gradient, on its approach to the ground it turns up the plane of its wing against the air; this checks its descent, and it lands gently.

F. H. Wenham.

(*To be continued.*)

...would like to make an obser-

AERIAL FLIGHT.

[17800.]—The subject of aërial flight is now attracting much attention from your correspondents, some of whom appear to be men of very considerable ability, well capable of seeing and discussing the question on theoretical grounds.

I have much to say ultimately on the subject myself, but I should have so often to quote or refer to the experiments described in the following paper that it has occurred to me that you might be willing to publish the paper itself, as it is out of print, and has never been transcribed beyond the reports of the Society, so that it would be quite new to most of your readers.

F. H. Wenham.

At the first meeting of the Aëronautical Society, held at the great room of the Society of Arts, on the 27th of June, 1866, His Grace the Duke of Argyll in the chair. The following paper was read by F. H. Wenham, Esq., C.E.:—

"On Aerial Locomotion and the Laws by which Heavy Bodies Impelled through Air are Sustained."

The resistance against a surface of a defined area, passing rapidly through yielding media, may be divided into two opposing forces. One arising from the cohesion of the separated particles; and the other from their weight and inertia, which, according to well-known laws, will require a constant power to set them in motion.

In plastic substances, the first condition, that of cohesion, will give rise to the greatest resistance. In water this has very little retarding effect, but in air, from its extreme fluidity, the cohesive force becomes inappreciable, and all resistances are caused by its weight alone; therefore, a weight, suspended from a plane surface, descending perpendicularly in air, is limited in the rate of fall by the weight of air that can be set in motion in a given time.

If a weight of 150lb. is suspended from a surface of the same number of square feet, the uniform descent will be 1,300 feet per minute, and the force given out and expended on the air, at this rate of fall, will be nearly six horse-power; and, conversely, this same speed and power must be communicated to the surface to keep the weight sustained at a fixed altitude. As the surface is increased, so does the rate of descent and its accompanying power, expended in a given time, decrease. It might, therefore, be inferred that, with a sufficient extent of surface reproduced, or worked up to a higher altitude, a man might by his exertions raise himself for a time, while the surface descends at a less speed.

A man, in raising his own body, can perform 4,250 units of work—that is, this number of pounds raised 1ft. high per minute—and can raise his own weight—say, 150lb.—22ft. per minute. But at this speed the atmospheric resistance is so small that 120,000 square feet would be required to balance his exertions, making no allowance for weight beyond his own body.

We have thus reasons for the failure of the many misdirected attempts that have, from time to time, been made to raise weights perpendicularly in the air by wings or descending surfaces. Though the flight of a bird is maintained by a constant reaction or abutment against an enormous weight of air in comparison with the weight of its own body, yet, as will be subsequently shown, the support upon that weight is not necessarily commanded by great extent of wing-surface, but by the direction of motion.

One of the first birds in the scale of flying magnitude is the pelican. It is seen in the lakes and estuaries of warm climates, fish being its only food. On the Nile, after the inundation, it arrives in flocks of many hundreds together, having migrated from long distances. A specimen shot was found to weigh twenty-one pounds, and measured ten feet across the wings, from end to end. The pelican rises with much difficulty, but, once on the wing, appears to fly with very little exertion, notwithstanding its great weight. Their mode of progress is peculiar and graceful. They fly after a leader, in one single train. As he rises or descends, so his followers do the same in succession, imitating his movements precisely. At a distance, this gives them the appearance of a long undulating ribbon, glistening under the cloudless sun of an Oriental sky. During their flight they make about seventy strokes per minute with their wings. This uncouth-looking bird is somewhat whimsical in its habits. Groups of them may be seen far above the earth, at a distance from the river-side, soaring, apparently for their own pleasure. With outstretched and motionless wings, they float serenely, high in the atmosphere, for more than an hour together, traversing the same locality in circling movements. With head thrown back, and enormous bills resting on their breasts, they almost fall asleep. A few easy strokes of their wings each minute, as their momentum or velocity diminishes, serves to keep them sustained at the same level. The effort required is obviously slight, and not confirmatory of the excessive amount of power said to be requisite for maintaining the flight of a bird of this weight and size. The pelican displays no symptom of being endowed with great strength; for when only slightly wounded it is easily captured, not having adequate power for effective resistance, but heavily flapping the huge wings, that should, as some imagine, give a stroke equal in vigour to the kick of a horse.

During a calm evening, flocks of spoonbills take their flight directly up the river's course; as if linked together in unison, and move by the same impulse, they alter not their relative positions, but at less than fifteen inches above the water's surface, they speed swiftly by with ease and grace inimitable, a living sheet of spotless white. Let one circumstance be remarked,—though they have fleeted past at a rate of near thirty miles an hour, so little do they disturb the element in which they move, that not a ripple of the placid bosom of the river, which they almost touch, has marked their track. How wonderfully does their progress contrast with that of creatures who are compelled to drag their slow and weary way against the fluid a thousandfold more dense, toiling in strong and eddying current beneath them.

Our pennant droops listlessly, the wished-for north wind cometh not. According to custom we step on shore, gun in hand. A flock of white herons, "buffalo-birds," almost within our reach, run a short distance from the pathway as we approach them. Others are seen perched in social groups upon the backs of the apathetic and semi-begrimed animals whose name they bear. Beyond the ripening sheaves of the crops which skirt the river-side, the land is covered with immense numbers of blue pigeons, flying to and fro in sheets, and searching for food with restless diligence. The musical whistle from the pinions of the wood-doves sounds cheerily, as they dart past with the speed of an arrow. Ever and anon are seen a covey of the brilliant, many-coloured partridges of the district, whose long and pointed wings give them a strength and duration of flight that seems interminable, alighting at distances beyond the possibility of marking them down, as we are accustomed to do with their plumper brethren at home. But still more remarkable is the spectacle which the sky presents. As far as the eye can reach it is dotted with birds of prey of every size and description. Eagles, vultures, kites and hawks, of unnumbered species, down to the small, swallow-like, insectivorous hawk common in the Delta, which skims the surface of the ground in pursuit of its insect prey. None seem bent on going forward, but all are soaring leisurely round over the same locality, as if the invisible element which supports them were their medium at rest as well as motion. But mark that object sitting in solitary state in the midst of yon plain; what a magnificent eagle! An approach to within eighty yards arouses the king of birds from his apathy. He partly opens his enormous wings, but stirs not yet from his station. On gaining a few feet more he begins to walk away, with half-expanded but motionless wings. Now for the chance fire! A charge of No. 3 from 11 bore rattles audibly but ineffectively upon his densely feathered body; his walk increases to a run, he gathers speed with his slowly-waving wings, and eventually leaves the ground. Rising at a gradual inclination, he mounts aloft and sails majestically away to his place of refuge in the Lybian range, distant at least five miles from where he rose. Some fragments of feathers denote the spot where the shot had struck him. The marks of his claws are traceable in the sandy soil, as, at first with firm and clenched digs, he forced his way, but as he lightened his body and increased his speed with the aid of his wings, the imprints of his talons gradually merged into long scratches. The measured distance from the point where these vanished, to the place where he had stood, proved that with all the stimulus that the shot must have given to his exertions, he had been compelled to run full twenty yards before he could raise himself from the earth.

Again the boat is under way, though the wind is but just sufficient to enable us to stem the current. An immense kite is soaring overhead, scarcely higher than the top of our lateen yard, affording a fine opportunity for contemplating his easy and unlaboured movements. The cook has now thrown overboard some offal. With a scream swoops the bird descends and seizes it in his talons. How easily he rises again with motionless expanded wings, the mere force and momentum of his descent serving to raise him again to more than half-mast high. Observe him next, with lazy flapping wings, and head turned under his body; he is placidly devouring the pendant morsel from his foot, and calmly gliding onwards.

The Nile abounds with large aquatic birds of almost every variety. During a residence upon its surface for nine months out of the year, immense numbers have been seen to come and go, for the majority of them are migratory. Egypt being merely a narrow strip of territory, passing through one of the most desert parts of the earth, and rendered fertile only by the periodical rise of the waters of the river, it is probable that these birds make it their grand thoroughfare into the rich districts of Central Africa.

On nearing our own shores, steaming against a moderate head-wind, from a station abaft the wheel the movements of some half-dozen gulls are observed, following in the wake of the ship, in patient expectation of any edibles that may be thrown overboard. One that is more familiar than the rest comes so near at times that the winnowing of his wings can be heard; he has just dropped astern, and now comes on again. With the axis of his body exactly at the level of the eyesight, his every movement can be distinctly marked. He approaches to within ten yards, and utters his wild plaintive note, as he turns his head from side to side, and regards us with his jet black eye. But where is the angle or upward rise of his wings, that should compensate for the descending tendency, in a yielding medium like air? The incline cannot be detected, for, to all appearance, the wings are edgewise, or parallel to his line of motion, and he appears to skim along a solid support. No smooth-edged rails, or steel-tired wheels, with polished axles revolving in well oiled brasses, are needed here for the purpose of diminishing friction, for Nature's machinery has surpassed them all. The retarding effects of gravity in the creature under notice, are almost annulled, for he is gliding forward upon a frictionless plane. There are various reasons for concluding that the direct flight of many birds is maintained with a much less expenditure of power, for a high speed, than by any mode of progression.

The first subject for consideration is the proportion of surface to weight, and their combined effect in descending perpendicularly through the atmosphere. The datum is here based upon the consideration of safety, for it may sometimes be needful for a living being to drop passively, without muscular effort. One square foot of sustaining surface, for every pound of the total weight, will be sufficient for security.

According to Smeaton's table of atmospheric resistances, to produce a force of one pound on a square foot, the wind must move against the plane (or, which is the same thing, the plane against the wind), at the rate of twenty-two feet per second, or 1,320ft. per minute, equal to fifteen miles per hour. The resistance of the air will now balance the weight on the descending surface, and, consequently, it cannot exceed that speed. Now, twenty-two feet per second is the velocity acquired at the end of a fall of eight feet—a height from which a well-knit man or animal may leap down without much risk of injury. Therefore, if a man with parachute weigh together 143lb., spreading the same number of square feet of surface contained in a circle fourteen and a half feet in diameter, he will descend at perhaps an unpleasant velocity, but with safety to life and limb.

It is a remarkable fact how this proportion of wing-surface to weight extends throughout a great variety of the flying portion of the animal kingdom, even down to hornets, bees, and other insects. In some instances, however, as in the gallinaceous tribe, including pheasants, this area is somewhat exceeded, but they are known to be very poor flyers. Residing as they do chiefly on the ground, their wings are only required for short distances, or for raising them or easing the descent from their roosting-places in forest-trees, the shortness of their wings preventing them from taking extended flights. The wing-surface of the common swallow is rather more than in the ratio of two square feet per pound, but having also great length of pinion, it is both swift and enduring in its flight. When on a rapid course this bird is in the habit of furling its wings into a narrow compass. The greater extent of surface is probably needful for the continual variations of speed and instant stoppages requisite for obtaining its insect food.

On the other hand, there are some birds, particularly of the duck tribe, whose wing-surface but little exceeds half a square foot, or seventy-two inches per pound, yet they may be classed among the strongest and swiftest of flyers. A weight of one pound, suspended from an area of this extent, would acquire a velocity due to a fall of sixteen feet—a height sufficient for the destruction or injury of most animals. But when the plane is urged forward horizontally, in a manner analogous to the wings of a bird during flight, the sustaining power is greatly influenced by the form and arrangement of the surface.

In the case of perpendicular descent, as a parachute, the sustaining effect will be much the same, whatever the figure of the outline of the superficies may be, and a circle perhaps affords the best resistance of any. Take, for example, a circle of twenty square feet (as possessed by the pelican) loaded with as many pounds. This, as just stated, will limit the rate of perpendicular descent to 1,320ft. per minute. But, instead of a circle sixty-one inches in diameter, if the area is bounded by a parallelogram ten feet long by two feet broad, and whilst at perfect freedom to descend perpendicularly, let a force be applied exactly in a horizontal

ONDON, FRIDAY, OCTOBER 22, 1880.

SCIENTIFIC AËROSTATION.

LTHOUGH the art of traversing the air by means of balloons has received a large amount [c]areful scientific attention ever since its earliest [deve]lopment, it has made but modest progress to[wards] attaining the position which has often been [pred]icted, and sometimes claimed for it, namely, [that] of general practical utility. We of course [exclude] from present consideration the notion of the [ball]oon, aërostat, aërial ship, or whatever other [name] it may be called by, forming a ready method [of tr]ansport for passengers and merchandise through [the] air in any direction at the will of man, as being [imp]racticable under existing natural laws. We [sim]ply take the balloon as it now exists, and we find [it to] be very much the machine it was when first [rend]ered practically available for ascents about one [hun]dred years ago, its sphere of usefulness having [been] but slightly extended, and its real services in [the] cause of science being of but very recent date. [It m]ay be objected that the development of the balloon itself is of but comparatively recent date, and [that] we are therefore expecting too much from it, or [at l]east that our remarks as to its slow progress are [som]ewhat premature. Let us then briefly glance at [its h]istory, and we shall see whether or not these [obje]ctions are altogether valid. The discovery by [Cav]endish in 1766 of the remarkable lightness of [hyd]rogen gas may be taken as the germ of the [inve]ntion of the balloon, whilst Professor Black of [Edi]nburgh may be credited with the application of [the] idea, inasmuch as he procured a thin animal [mem]brane which he proposed to inflate with this gas [to] test its ascensional powers, although he never [com]pleted the experiment. In 1772 Cavallo followed [up] the notion by inflating swines' bladders, but he [arri]ved at no practical results. The Brothers Montgolfier perfected the idea and really invented the [bal]loon; but the first attempt to render it of practical [util]ity did not take place until 1794, during the Wars [of] the Revolution. At that time an aërostatic Instituti]on was formed at Meudon, near Paris, and at [the] battle of Fleurus, near Charleroi, a balloon in [cha]rge of a corps of "aërostiers" from Meudon [ren]dered signal service. Balloons have since been [simi]larly employed, and the question of military [bal]looning continues to command the attention of [our] own and other Governments.

[T]he first attempt to enlist the service of balloons [sol]ely in the interests of science was made on the [18th] of July, 1803, when Robertson and Lhoest made [an a]scent at Hamburg. The results of their observati]ons were considered to be of such importance [that] the French Institute arranged for further ascents, [whi]ch were made in 1804 by MM. Biot and Gay-[Lus]sac. They, however, failed to confirm the results [obta]ined by Robertson and Lhoest, and science [rece]ived but little assistance from the balloon from [tha]t time until about seventeen years since. In the [inte]rim, however, a few scientific aërial voyages were [und]ertaken, notably those of Humboldt, in America, [of R]ush and Green, in England, in 1847-9, on behalf [of t]he British Association, and of Barral and Bixio, [in] Paris, in 1850. No very important results accrued, [and] the contributions of balloons to positive science [may] be set down at almost nothing until about 1863, [whe]n Mr. James Glaisher communicated to the [Roy]al Institution the results of eight ascents he had [ma]de for the purposes of scientific research. His [rev]elations awakened a new interest in, and gave a [fres]h impulse to, aëronautics. He subsequently made [a g]reat number of ascents, and as a result has added [man]y interesting and important facts to the annals of [phy]sical science, and which he has communicated [to] the Royal Institution. But with all this, and [alth]ough the balloon has rendered important aid to [scie]nce, its practical utility would appear to be con[fined] within these limits, and those of military obser[vat]ion, and the fulfilment of the predictions of its [gen]eral utilisation appear to be very remote notwith[stan]ding its century of existence. We do not, of [cou]rse, deny to the balloon the position of import[ance] it occupies as an invention, and which position it will continue to occupy, even though it remains an isolated power. But at the same time we hold that it has as yet failed to fulfil the mission which has been claimed for it, of becoming a means of practical everyday usefulness. Nor do we at present see any chance of its general practical utility.

We have been led to discuss the present subject by reason of our having been charged of late with having manifested a lack of interest in the proposed Arctic balloon expedition and with undue reticence with regard to the Balloon Society of Great Britain, which has recently sprung into existence. Now we confess to being of an essentially practical turn of mind, and we do not mind owning our inability to discover anything very practical, or perhaps practicable, in either the expedition or the society. The aim and end of the expedition are now well known, and all we can say is that, if the necessary funds are forthcoming and the expedition is started, we shall heartily wish it success. With regard to the society, that is already established and working; so by its works it may be judged. But we are by no means clear as to what its precise objects are. It has, we presume, been established for the advancement of aëronautical science; but some years ago a society—the Aëronautical Society of Great Britain—was established for a similar purpose, and we believe it is still in existence and doing all the work that can fall within the province of such a society, or, if it is not, it should be. We are not aware that the Balloon Society has any higher or more practical aims than the older institution, nor can we find evidence of this from its action. It holds meetings, at which papers are read and discussed, and it has organised several aëronautical excursions. In all this, however, we fail to find, even from close inquiry, that it has thrown any additional light upon science, or has enriched its annals by the contribution of any new practical results. The most recent of its exploits is the organisation of the International Balloon Contest at the Crystal Palace, which was to have taken place on Wednesday last. As it was stated that some important scientific results were to be the outcome, we, in the interests of science, were desirous of seeing the start, ascertaining the direction of the intended researches, and in due time of recording the results. We therefore repaired to the Crystal Palace on the day stated, but cannot say that the visit afforded us unmixed satisfaction.

The two balloons which were to take part in the contest belong, one to the Balloon Society and the other to the Académie d'Aérostation Météorologique de Paris. The former has a capacity of 28,000 cubic feet, and was in charge of Mr. T. Wright, as aëronaut, and the latter a capacity of 42,000 cubic feet, M. Wilfrid de Fonvielle being the French aëronaut. The Lord Mayor of London and the leading civic dignitaries of Paris and Brussels were present to witness the ascent, which was fixed to take place at three o'clock, and great was to have been the ceremonial. But the Fates were—or rather the weather was—unpropitious, and in consequence of a fall of snow and rain the ascent was postponed to the following day—yesterday, when it took place.

So far it was unfortunate, although it does not augur well for the future of ballooning from a practical point of view if ascents are to be controlled by variations of weather. Desirous of learning the precise scientific objects of the ascent, we addressed ourselves to the authorities of the Balloon Society, and ascertained in the first place that it was to be a sort of balloon race in which the machine that travelled the greatest distance was to be the victor. Beyond this, certain meteorological observations were to be made; but upon the nature of these observations, and as to whether any new points were to be investigated, or anything attempted which had not previously been tried, we failed to elicit any definite or precise information. All we could learn was that the differences in speed and temperature between air-currents at various altitudes were to be noted. The practical outcome of all this, we were told, on further inquiry, was to be the demonstration that the balloon was available as a means for providing weather forecasts a fortnight in advance. Now it need hardly be pointed out that the expense of an aërial staff would be enormous, the practicability of the scheme, to say the least, highly problematical—especially if ascents are dependent upon the seasons—and the utility of the results very questionable. We are therefore justified in maintaining that both from a scientific and a practical point of view, and judged by its works generally, the Balloon Society does not make out a remarkably strong case for support; whilst, with regard to the International Balloon Contest, we are inclined to the opinion that the most, if not the only, practical results that will accrue will be a respectable addition to the exchequer of the Crystal Palace Company. And we sincerely hope it may prove to be so.

AERIAL FLIGHT.

(*Continued from page 113.*)

[17061.]—It has before been shown how utterly inadequate the mere perpendicular impulse of a plane is found to be in supporting a weight, when there is no horizontal motion at the time. There is no material weight of air to be acted upon, and it yields to the slightest force, however great the velocity of impulse may be. On the other hand, suppose that a large bird, in full flight, can make forty miles per hour, or 3,520ft. per minute, and perform one stroke per second. Now, during every fractional portion of that stroke, the wing is acting upon and obtaining an impulse from a fresh and undisturbed body of air; and if the vibration of the wing is limited to an arc of two feet, this by no means represents the small force of action that would be obtained when in a stationary position, for the impulse is secured upon a stratum of fifty-eight feet in length of air at each stroke. So that the conditions of weight of air for obtaining support equally well apply to weight of air, and its reaction in producing forward impulse.

So necessary is the acquirement of this horizontal speed, even in commencing flight, that most heavy birds, when possible, rise against the wind, and even run at the top of their speed to make their wings available, as in the example of the eagle, mentioned at the commencement of this paper. It is stated that the Arabs, on horseback, can approach near enough to spear these birds, when on the plain, before they are able to rise: their habit is to perch on an eminence, where possible.

The tail of a bird is not necessary for flight. A pigeon can fly perfectly with this appendage cut short off: it probably performs an important function in steering, for it is to be remarked that most birds that have either to pursue or evade pursuit are amply provided with this organ.

The foregoing reasoning is based upon facts, which tend to show that the flight of the largest and heaviest of all birds is really performed with but a small amount of force, and that man is endowed with sufficient muscular power to enable him also to take individual and extended flights, and that success is probably only involved in a question of suitable mechanical adaptations. But if the wings are to be modelled in imitation of natural examples, but very little consideration will serve to demonstrate its utter impracticability when applied in these forms. The annexed diagram, Fig. 1, would be about the proportions needed for a man of medium weight. The wings, *a a*, must extend out sixty feet from end to end, and measure four feet across the broadest part. The man, *b*, should be in a horizontal position, encased in a strong framework, to which the wings are hinged at *c c*. The wings must be stiffened by elastic ribs, extending back from the pinions. These must be trussed by a thin band of steel, *e e*, Fig. 2, for the purpose of diminishing the weight and thickness of the spar. At the front, where the pinions are hinged, there are two levers attached, and drawn together by a spiral spring, *d*, Fig. 2, the tension of which is sufficient to balance the weight of the body and machine, and cause the wings to be easily vibrated by the movement of the feet acting on treadles. This spring serves the purpose of the pectoral muscles in birds. But with all such arrangements the apparatus must fail—length of wing is indispensable; and a spar thirty feet long must be strong, heavy, and cumbrous; to propel this alone through the air, at a high speed, would require more power than any man could command.

In repudiating all imitations of natural wings, it does not follow that the only channel is closed in which flying mechanism may prove successful. Though birds do fly upon definite mechanical principles, and with a moderate exertion of force, yet the wing must necessarily be a vital organ and member of the living body. It must have a marvellous self-acting principle of repair, in case the feathers are broken or torn; it must also fold up in a small compass, and form a covering for the body.

These considerations bear no relation to artificial wings; so in designing a flying-machine, any deviations are admissible, provided the theoretical conditions involved in flight are borne in mind.

Having remarked how thin a stratum of air is displaced beneath the wings of a bird in rapid flight, it follows that in order to obtain the necessary *length* of plane for supporting heavy weights, the surface may be superposed, or placed in parallel rows, with an interval between them. A dozen pelicans may fly one above the other without mutual impediment, as if framed together; and it is thus shown how two hundredweight may be supported in a transverse distance of only ten feet.

In order to test this idea, six bands of stiff paper, three feet long and three inches wide, were stretched at a slight upward angle, in a light rectangular frame, with an interval of three inches between them, the arrangement resembling an open Venetian blind. When this was held against a breeze, the lifting power was very great, and even by running with it in a calm it required much force to keep it down. The success of this model led to the construction of one of a sufficient size to carry the weight of a man. Fig. 3 represents the arrangement. *a a* is a thin plank, tapered at the outer ends, and attached at the base to a triangle, *b*, made of similar plank, for the insertion of the body. The boards, *a a*, were trussed with thin bands of iron, *c c*, and at the ends were vertical rods, *d d*. Between these were stretched five bands of holland, fifteen inches broad and sixteen feet long, the total length of the web being eighty feet. This was taken out after dark into a wet piece of meadow land, one November evening, during a strong breeze, wherein it became quite unmanageable. The wind acting upon the already tightly-stretched webs, their united pull caused the central boards to bend considerably, with a twisting, vibratory motion. During a lull, the head and shoulders were inserted in the triangle, with the chest resting on the baseboard. A sudden gust caught up the experimenter, who was carried some distance from the ground, and the affair falling over sideways, broke up the right-hand set of webs.

In all new machines we gain experience by repeated failures, which frequently form the stepping-stones to ultimate success. The rude contrivance just described (which was but the work of a few hours) had taught, first, that the webs, or aëroplanes, must not be distended in a frame, as this must of necessity be strong and heavy, to withstand their combined tension; second, that the planes must be made so as either to furl or fold up, for the sake of portability.

In order to meet these conditions, the following arrangement was afterwards tried:—*a a*, Figs. 4 and 5, is the main spar, sixteen feet long, half an inch thick at the base, and tapered, both in breadth and thickness, to the end; to this spar was fastened the panels *b b*, having a base-board for the support of the body. Under this, and fastened to the end of the main spar, is a thin steel tie-band, *e e*, with struts starting from the spar. This served as the foundation of the superposed aëroplanes, and, though very light, was found to be exceedingly strong; for when the ends of the spar were placed upon supports, the tabular bore the weight of the body without any strain or deflection; and further, by a separation at the base-board, the spars could be folded back, with a hinge, to half their length. Above this were arranged the aëroplanes, consisting of six webs of thin holland, fifteen inches broad; these were kept in parallel planes, by vertical divisions, two feet wide, of the same fabric, so that when distended by a current of air, each two feet of web pulled in opposition to its neighbour; and finally, at the ends (which were each sewn over laths), a pull due to only two feet had to be counteracted, instead of the strain arising from the entire length, as in the former experiment. The end-pull was sustained by vertical rods, sliding through loops on the transverse ones at the ends of the webs, the whole of which could fall flat on the spar, till raised and distended by a breeze. The top was stretched by a lath, *f*, and the system kept vertical by staycords, taken from a bowsprit carried out in front, shown in Fig. 6. All the front edges of the aëroplanes were stiffened by bands of crinoline steel. This series was for the supporting arrangement, being equivalent to a length of wing of ninety-six feet. Exterior to this, two propellers were to be attached, turning on spindles just above the back. They are kept drawn up by a light spring, and pulled down by cords or chains, running over pulleys in the panels *b b*, and fastened to the end of a swivelling cross-yoke, sliding on the base-board. By working this cross-piece with the feet, motion will be communicated to the propellers, and by giving a longer stroke with one foot than the other, a greater extent of motion will be given to the corresponding propeller, thus enabling the machine to turn, just as oars are worked in a rowing boat. The propellers act on the same principle as the wing of a bird or bat: their ends being made of fabric, stretched by elastic ribs, a simple waving motion up and down will give a strong forward impulse. In order to start, the legs are lowered beneath the base-board, and the experimenter must run against the wind.

An experiment recently made with this apparatus developed a cause of failure. The angle required for producing the requisite supporting power was found to be so small, that the crinoline steel would not keep the front edges in tension. Some of them were borne downwards, and more on one side than the other, by the operation of the wind, and this also produced a strong fluttering motion in the webs, destroying the integrity of their plane surfaces, and fatal to their proper action.

Another arrangement has since been constructed, having laths sewn in both edges of the webs, which are kept permanently distended by cross-stretchers. All these planes are hinged to a vertical central board, so as to fold back when the bottom ties are released, but the system is much heavier than the former one, and no experiments of any consequence have as yet been tried with it.

It may be remarked that although a principle is here defined, yet considerable difficulty is experienced in carrying the theory into practice. When the wind approaches to fifteen or twenty miles per hour, the lifting power of these arrangements is all that is requisite, and, by additional planes, can be increased to any extent; but the capricious nature of the ground-currents is a perpetual source of trouble.

Great weight does not appear to be of much consequence, if carried in the body; but the aëroplanes and their attachments seem as if they were required to be very light, otherwise they are awkward to carry, and impede the movements in running and making a start. In a dead calm, it is almost impracticable to get sufficient horizontal speed, by mere running alone, to raise the weight of the body. Once off the ground, the speed must be an increasing one, if continued by suitable propellers. The small amount of experience as yet gained, appears to indicate that if the aëroplanes could be raised in detail, like a superposed series of kites, they would first carry the weight of the machine itself, and next relieve that of the body.

Until the last few months no substantial attempt has been made to construct a flying-machine, in accordance with the principle involved in this paper, which was written seven years ago. The author trusts that he has contributed something towards the elucidation of a new theory, and shown that the flight of a bird in its performance does not require that enormous amount of force usually supposed, and that in fact birds do not exert more power in flying than quadrupeds in running, but considerably less; for the wing movements of a

AERONAUTICAL SOCIETY OF GREAT BRITAIN.

THE Annual General Meeting of this Society was held at the Society of Arts' room on Monday night. The chair was taken by Mr. James Glaisher, F.R.S., who remarked that he regretted he could not speak of more important results. Mr. Infield, who had made a large shield a year since, had constantly been at work on it ever since, but was not satisfied with its present condition, and, therefore, reserved its exhibition for another occasion. He had hoped to have told them that balloons had been used for photographing the country, especially as the plates could now be prepared weeks beforehand, need only be exposed for a few seconds, and could be kept for a lengthened period before development; but these anticipations yet remained unfulfilled.

Mr. W. H. Phillips showed a model of a new flying-machine he was making, and read a paper describing it. He said the requirements for artificial flight were (1) that the expanse of wing-surface should be sufficient to sustain the whole weight in easy descent; (2) that the wing-surface needed might be provided by two large wings, or by many smaller wings equal thereto; (3) that lightness and strength were indispensable; (4) that the down-stroke of wing must be sufficient in force to sustain and propel horizontally the whole weight; and (5) the down-stroke, if intermittent, must be rapid, as otherwise the whole apparatus descends between the intervals of stroke. Acting on these principles, he had projected an apparatus which he had made to considerable size, employing an impetus of thirteen million pounds of steam. Of it he showed a model, consisting of an elementary skeleton in rigid steel wire for one long, slightly curved, and narrow wing; the frame was clothed with a series of loose cambric "feathers," oblong in form, hung from the ridge transversely. The whole weighed 4oz., but required a weight of 4lb. to move it up or down. However, by counterpoising the wing with another it could be more easily moved, and he proposed to increase the number of these wings and to employ steam-power for levitation. A short discussion followed, in which Mr. Moy remarked that however easily the wings might be balanced, Mr. Phillips would need a good balance at his banker's to construct a working model.

The Secretary (Mr. F. W. Brearey) read a communication from Mr. S. E. Peal, of Sapakati, Sibsagur, Assam, on "The Flotation of Large Birds and Balloons." The writer stated that he had written to the ENGLISH MECHANIC on the "Flotation and Soaring of Birds"—a subject which he thought he had unusual opportunities of observing. It did not seem to be understood in England that large birds could not only float without flapping the wings for long periods without coming down, but actually rise thus to elevations of some 1,000 to 6,000 or 8,000ft. The bird, when thus soaring, seemed perfectly motionless, and could easily be followed and watched by a good telescope; in all cases the wings were fully extended rigidly. The pelican, adjutant, cyrus, and vulture all soared in this way. They invariably rose from the ground by flapping the wings vigorously; they did not soar and float, unless there was some wind; they could not soar or float in a calm, wind being needful; generally by rising they described a circular spiral track, a track which in the main seemed to tend to leewards. They had in Assam two steady winds, the N.N.E. and W.S.W. often blowing at once, one over the other alternating; birds would go some way in one and gradually return in the other. The birds were never seen to move in right lines for any distance, unless coming down. It was highly probable that the birds slept or dozed when soaring, and collision was not likely because of the tend vibration of the feather-tips. The solution of the question of soaring seemed of value, as it involved a minimum of muscular exertion, say 1-10th that of flying. The difference appeared to be that, in flying, not only the friction of passage horizontally through the air had to be overcome, but the power needed to overcome gravitation; whereas, in soaring, which generally took place at high speeds, the wing-surfaces passed through the air and over a stratum of it as the latter could be set in motion, as if it were rigid sheet-glass, on which the wings skated, *à la* boomerang. Thus the usual effects of gravitation were not seen, and birds that soared needed long narrow wings, while those that only flew had shorter and wider wings. The wing-surface narrowing as speed increased, would seem to indicate a useful direction to work in, the same applying to any form of screw for aerial propulsion. The support was also apparently more effective at or near the tips than close to the body, due, perhaps, to passing through a less disturbed state. By the ENGLISH MECHANIC of April 15th last, p. 131, the writer found that a law which he had discovered some years ago when investigating the flight of pickets or long bullets, did not appear to be yet known as well as it should be. It was illustrated in the ENGLISH MECHANIC about three years ago. It was only possible to keep an oblong balloon end on to the wind when it was anchored by the end; when free to move, the balloon (unless going at precisely the same speed as the air), eventually and certainly placed itself at right angles to its line of progress. The law which compelled this was both simple and universal; and it could easily be seen in paper models of suitable forms suspended by a thread in a draught of air. In the case of a long bullet, which was a very heavy body compared to its size, it was found necessary to make it spin rapidly on its long axis, to avoid "overstelling" from pressure on the point. The amount of point necessary to prevent "overset" in such a small body as a bullet, was very great compared to its size, and in such a large body as a balloon would greatly exceed its levitating power, if wholly used for this purpose. With a knowledge of this law he asserted that experiments on a large scale were simply wasted money and time. The two principles of penetrating resisting media were typified by the arrow and the picket bullet; the former flew point on during its entire flight, whereas in the latter the axis of direction remained constant. Theoretically and practically, an oblong balloon was simply a means of increasing instead of diminishing the area of resistance; the power needed to prevent "overset," whether got from a skeleton screw at high speed, or in any other way, would be far more than the balloon could lift as machinery. The law might be stated thus: "All bodies tend naturally to place their greatest area of resistance to any resisting medium." Lately the author had written to the Secretary of the Royal Geographical Society suggesting that the peculiarly steady and regular N.N.E. and W.S.W. winds prevalent in Assam during most of the year were eminently suitable for exploring the inaccessible country by balloon, and for photographing it and mapping it out. The whole of Bengal could be surveyed by taking advantage of the same winds. The Chairman, in proposing a vote of thanks to Mr. Peal, expressed his gratification that that gentleman had conveyed the result of his observations on Oriental wind-currents and the flight of tropical birds to the public in the ENGLISH MECHANIC. Mr. Douglas Scoffern read a *résumé* of what had been done in aërial navigation, in which he advocated the more attentive study of parachutes, which led to an animated and personal discussion between Mr. Simmons, Mr. Moy, and the reader of the paper.

Herald. Sept. 8. 1881.

AERIAL NAVIGATION.

Proposed Voyage from Minnesota to the Atlantic Seaboard.

SCIENTIFIC RESULTS EXPECTED.

The United States Signal Service To Be Represented on the Trip.

[BY TELEGRAPH TO THE HERALD.]

MINNEAPOLIS, Minn., Sept. 6, 1881.

Everything is ready for the King balloon voyage from this city to the Atlantic seaboard but the weather. The wind has been blowing steadily all the morning from west to east, exactly opposite to the breeze we need. Rain is falling in torrents, and the Minnesota hills are hid in mists. The start has been postponed till Friday. It is likely, however, that the general meteorological conditions may change within the next ten hours in our favor. Upon the heels of the storm a stiff northwestern wind is looked for, and the United States Signal Station at St. Paul predicts clear and cool weather for to-morrow afternoon. If this prophecy turns out to be true it is likely that the balloon expedition will prove one of the most remarkable scientific experiments of the nineteenth century.

THE AERIAL TOURISTS.

The party who are to make the trip consist of Professor Samuel A. King, the aeronaut; Mr. W. G. Nicholas, of the Chicago *Times*; Mr. Luther L. Holden, of the Boston *Journal*; Mr. Winslow Upton, of the United States Signal Service; Mr. E. H. Johnston, of the St. Paul and Minneapolis *Pioneer Press*; Mr. Charles M. Fays, of the Minneapolis *Tribune*, and your correspondent. To-day we signed an agreement to the effect that Professor King shall be absolute commander of the balloon and its occupants, and whenever it becomes necessary for one of the company to leave the car at any stage of the journey the person designated by the commander shall obey without demur. This document provided that the dropped man should be "cheerful" about it, but as some one is likely to be suddenly left in the middle of a forest, perhaps a hundred miles from the nearest settlement, the correspondents refused to sign until the objectionable word was withdrawn. Each man is provided with a complete suit of rubber clothing, a compass, automatic lamp and flask of corn juice, to guard against snake bites.

A MONSTER BALLOON.

The ascension will take place from the grounds of the Minneapolis Agricultural and Mechanical Fair. A great amphitheatre has been erected which is capable of seating 20,000 people. It is over a quarter of a mile long, and in the centre on the wet grass lies the great balloon ready for inflation, except that it will have to be turned inside out and the machinery adjusted. Alongside of it are ranged several large wooden cylindrical tanks, from which the gas is to be obtained to generate the necessary 3,000,000 feet of hydrogen. On 24,000 pounds of iron scraps will be poured 24,000 pounds of sulphuric acid, the former being stored in the tanks, while 12,000 pounds of lime will be used in purifying and 11,000 pounds of ice in cooling the gas. The enormous bag which is to hold the gas is of a peculiar rubber cloth, made expressly for the purpose. Two sheets of cambric received sixty coats of this rubber varnish each and were then fused into a sort of Mackintosh cloth by iron rollers. The material is very tight and will prevent the percolation of the gas. It has been tested and stood a heavy pressure before air was forced through its pores. This is an important step toward success, as hydrogen can leak through a very fine texture. The cloth to the balloon is doubled, except at the top, where it is trebled, as the upward tendency of the gas puts the greatest strain upon the upper part. There are sixty-two gores or segments, each ninety-five feet long and thirty-five inches at the lower portion. Each seam has three rows of stitching cemented with rubber.

PREPARATIONS FOR AN EMERGENCY.

The copper throttle valve is of the most improved make and will be fastened securely in the top of the balloon. The usual "rip rope," or collapsing cord, is sewed into one of the seams and the end hangs down through the neck of the balloon in the car, so that at a moment's notice the whole structure can be ripped open from top to bottom. The balloon is 186 feet in circumference and ninety-five feet in height, and the netting is spun from the finest hemp and cotton. The car is an ordinary oval wicker basket. In no other respects is the balloon remarkable, except that it has been built with greater care than any other structure of the same kind. The expedition is the most laborious one that has ever been organized in this country.

SCIENTIFIC FEATURES OF THE TRIP.

General Hazen, Chief of the United States Signal Service, has detailed Mr. Upton to accompany the party and make a report to the government at the termination of the voyage. This is the most important feature of all, as the scientific result of the trip will depend upon the accuracy of his observations. He has been assistant in the observatories at Cambridge, Cincinnati and Washington. He was the first assistant to Professor Abbe in the scientific branch of the service at Washington, and in that capacity computed an order of the recent comet. Mr. Upton has been instructed to particularly observe the direction and force of the air currents, besides the temperature and distribution of moisture. If the balloon rises above the clouds his orders are to locate its position by means of a sextant, which will be carried in the car. This is the first time that an attempt has been made to use a sextant in the air, and if it succeeds the scientific world will have gained something. The Washington signal station will be notified at the moment the balloon starts, and for eighteen hours afterward every government signal station east of Dakota and as far south as Virginia will take hourly observations in harmony with Mr. Upton. The instruments he will take with him are two barometers, a hygrometer, a Dupont apparatus, a wet bulb thermometer, three dry bulb thermometers, a solar radiation thermometer, a minimum thermometer, an air meter and a sextant. Besides these he has an apparatus invented expressly for this journey. It is a Japanese instrument so balanced that it will indicate whether the balloon is going downward or upward and show the velocity at which it is moving. Edison has sent out an electric light which will be attached to the car and used at night if the moon is obscured by clouds.

PROFESSOR KING'S THEORIES.

Professor King has two theories that will be tested, if possible, by Mr. Upton. One is that clouds cause some kind of attraction for balloons. The other is between areas of high pressure and areas of low pressure. There are between them plains of vapor which can neither be seen from above nor below, but which are perfectly discernible when the balloon has reached their level. This vapor shoots out in such a peculiar manner that the Professor is inclined to believe the Aurora Borealis is caused by it. Everything will be put to an actual physical test. Mr. Upton has compared his instruments with those at the St. Paul Signal Station and found them true. According to instructions he will make a similar comparison at the nearest station to the final landing. The gradual change in the air as the lakes are crossed or as the ocean is approached will be carefully noted down.

CONTINGENCIES PROVIDED FOR.

We will want to start at a pretty fair altitude, as Minneapolis is over eight hundred feet above the sea level, and the balloon will have to rise at least four thousand feet to escape the surface disturbances. The beginning of the voyage may be discouraging on account of the mountainous character of the country, but if we can clear Lake Michigan we have good prospects of reaching the seaboard. If the wind is blowing strongly toward the north we will not start, as the party would be landed in Lake Superior in a few hours. Lest we should be dipped in any of the lakes fifty hermetically sealed cans have been sewed in a bag and fastened under the seat of the car, so that it will float. The car will contain 200 pounds of rations, including 150 pounds of canned meats, chicken, turkey, and a supply of "hard tack." A large quantity of liquid comforts will also be taken, and 500 pounds of sand ballast. On account of the rain the balloon was not painted. In the language of the late William Nye," its name, "it shall be nameless." It is simply a great white globe. There will be an attempt made to influence the course of the balloon, the idea being to trace the air currents and test the theory of the eastern movement of storms. A drag rope several hundred feet long will hang beneath the car, and to it will be attached a strong anchor. At any time, should a serious danger present itself, the balloon can be secured until the wind changes or the danger disappears. Apparatus for camping out and cooking in the woods will be taken with us. In this way the journey will be accomplished, even if it is impossible to do it at one bound.

UTILIZING THE ELECTRIC LIGHT.

One of the greatest difficulties in ballooning at night will be removed by the electric light, which will illuminate the scene sufficiently to allow the principal landmarks to be seen. This will preclude the possibility of our happening into a sheet of water for an anchorage in the darkness. Our voyage will extend over many lakes and rivers that lie scattered "from the bleak shores of the sea to the land where the Father of Waters seizes the hills in his hand and drags them down to the ocean." There are faint indications which would point to the Gulf of St. Lawrence as the destination of the expedition, if the ship floats long enough. But whether we will go northeast or southeast will be settled, I think, before we will pass Chicago, as the current seems to separate at Lake Michigan.

[BY TELEGRAPH TO THE HERALD.]

MINNEAPOLIS, Minn., Sept. 7, 1881.

The weather here is cold, but clearer than yesterday. The balloon expedition will start on Friday afternoon with good prospects. The Edison electric light apparatus, which is to be taken in the balloon car, has been tested and is an entire success.

ACCIDENT TO AN AERONAUT.

BOSTON, Mass., Sept. 7, 1881.

Professor Rogers, the aeronaut, made a balloon ascension at Point of Pines, a suburban summer resort, to-day. When the balloon had reached an altitude of 1,000 feet an upper seam ripped, allowing gas to escape and causing the balloon to descend rapidly. When within 100 feet of the ground the balloon collapsed, the car tipped and Professor Rogers fell to the ground at Nahant Beach, about a mile from the starting point. He was picked up unconscious, but soon rallied, and was carried to his home in Malden. He is thought to have sustained severe internal injuries.

Menlo Park Scrapbook, Cat. 1056

No. 40. "Various Electrical Appliances and Torpedo Experiments"

This scrapbook covers the years 1873-1881. It contains clippings about electrical devices, applications for electricity, electricity in war, and torpedoes. There is also one clipping about Edison's phonometer. The book contains 137 numbered pages.

Blank pages not filmed: 2-9.

Electric Fall-Machines.—M. Waldner.—These are for demonstrating the laws of falling bodies. In one arrangement a brass ball is hung by a thread some height above the ground. Under it, at distance = 1, are two metallic balls connected with the poles of an electric machine; they are so far apart that a spark cannot pass between them, but if the suspended ball drop between them a spark will pass. Further down, at distance = 4, then = 9, &c., are similar pairs of balls. The thread of the suspended ball being burnt, the latter falls between the successive pairs, giving passage at each pair, to the current, and simultaneously, the spark in another part of the circuit strikes a revolving soot-blackened drum, making a mark. The distances between successive marks are found to be equal. In a second arrangement, there are two cylindrical conductors, insulated and vertical, with a metallic ball suspended between them at the top, hardly filling the interval, and sufficient to enable a spark to pass between the cylinders, which are connected with the poles of an induction (secondary) coil. One of the cylinders has a coating of soot-blackened paper. The thread is burnt, and the ball falls; sparks are made to pass at regular intervals of time, by means of clockwork, interrupting the battery current. Each spark leaves its mark on the blackened surface; and thus are shown the spaces passed over in equal times.

Elect News Aug 19. /75

AN ELECTRIC PHOTOMETER.

Whoever (says Dr. Werner Siemens, in a paper recently read to the Verein für Gewerbfleiss) has gone thoroughly into the subject of Photometry, will have come to the conviction that it is still at a very low stage of development. It has not yet been once fixed what, exactly, we have to measure. Every solid body, we know, raised to high temperatures, emits light and heat-rays in all directions. According to the new theory it is ether waves, of all possible wave-lengths, which go out from the hot body. A portion of these waves excites in our retina, when it strikes it, the sensation of light. If short and long ether waves are in a proportion to each other, like that in which the sun or other very highly heated body emits them, we call the sensation of light we receive from them "white light." When, however, only light waves of a certain wave-length are admitted to our eye, our sensation of light is altered, and we name the light, red, yellow, blue, violet, according to the wave-length of the rays admitted. The prism, it is known, is a means by which the rays of a white bundle of light may be separated according to the wave-length. Since the impressions of the red, yellow, blue light are quite different on us, it is evidently quite impossible to compare together the intensities of such different sensations. The photometers hitherto made, however, are all on the principle of so regulating the action of the two light-sources to be compared, on an illuminated object, that the latter seems to our eye illuminated to an equal degree by the two sources. This method is best carried out by Bunsen's photometer, which is based on the fact that an oil-spot on a piece of white paper is no longer visible, when it is illuminated on both sides equally, strongly with white light. This is pretty accurate so long as both light sources send out white light, or at least light of the same colour. If the colours are different the spot does not disappear, and there is no means of comparison. There is, of course, still another criterion of light-strength, and it is properly the only correct one. We require light for the perception of objects, and that light is for us the best or brightest which enables us most distinctly to see the objects. One might hereupon construct a photometer quite independent of colour, by so regulating, in any way (*e.g.*, by diminishing the light-receiving surface of a lens), the strength of the two light sources, that the same object might be equally distinctly perceived with both. It would appear, however, that the eyes of different men are unequally receptive for differently coloured light, and are also soon fatigued, so that this otherwise rational method of light measurement, also, cannot yield constant results.

I have endeavoured to utilise electricity (that force which so often helps us when other forces fail), to measurement of light.

It is known that selenium—a substance standing on the boundary of the metals and metalloids, and possessing many remarkable physical properties—has two properties, which would seem to render it peculiarly suitable for the object in view. When selenium that has been quickly cooled—amorphous selenium—is heated to a temperature of 80° to 100°, the mass becomes crystalline, under development of heat, and a conductor of electricity, whereas in the amorphous state it is an insulator. Now, this crystalline selenium has the remarkable property—discovered and described by the English Lieut. Sale—of conducting electricity better when it is illuminated than when it is in darkness. Sale further found that the increase of the conductivity increases with the strength of the illumination, so that—in remarkable agreement with the retina of the eye—it is most strongly influenced by those parts of the spectrum which most affect the eye.

These remarkable properties I sought to turn to account in photometry. The initial difficulties—consisting partly in the small conductivity of crystalline selenium, its inconstancy, and the very weak and variable action of the light, partly in the disturbing influence of heat-rays—I succeeded in removing, inasmuch as, by long heating of amorphous selenium nearly to its melting-point, or by crystallising out from the slowly cooled molten mass, I prepared a modification of the crystallised selenium, which conducts much better, is much more influenced by light, is not essentially affected by heat-rays, and retains its properties pretty constant. It is especially notable that its conductivity *decreases* on heating, as in the case of metals, whereas in the other the conductivity *increases*, as in the case of conducting metalloids and electrolytes. By filling up the interval of two small flat spirals of wire with such coarsely crystalline selenium between two leaves of mica, I have succeeded in producing a photometric apparatus which—with a Daniell's cell or a small thermo-electric electromotor—gives sufficiently strong currents for one to be able to compare, by measurement of them, even very weak intensities of light with sufficient exactness.

The apparatus which I show you here is such an electric photometer. At the bottom of a small tube, which can be rotated, is some of the selenium preparation as described. The ends of the two spiral wires are connected with each other through a Daniell cell and the wire of a galvanometer. The needle is thus deflected. If I remove the cover of the tube, and admit the light of a gas-flame, whose strength I would measure, to the selenium disc, the conductivity of the disc increases proportionally to the strength of the light; so the deflection of the needle becomes greater. If I now turn the tube so that it is directed to a normal candle, instead of to the flame to be measured, and regulate the distance of this normal candle so that the deflection of the needle becomes and remains the same when the selenium is alternately illuminated by the flame to be measured and the normal candle, the light action is the same from both, and the light strengths are accordingly in inverse proportion to their distance from the selenium plate.

This instrument can be made with any degree of sensibility desired, and I hope that a practically serviceable apparatus may be developed from it. It will probably also become possible thus to indicate light strength graphically in a continuous matter, but many experiments are yet required in order to acquire a sufficient basis for this.

CONTROLLING AND CORRECTING CLOCKS BY ELECTRICITY.

A paper on this subject was read at the Society of Arts on Wednesday evening, 22nd inst., by Frederick J. Ritchie, Esq., of Messrs. J. Ritchie and Son, Edinburgh. He began by describing the system of time signals initiated by Greenwich Observatory, and sent to the principal towns of Great Britain, and noticed a few of the most successful results in the application of electricity to clocks, which might be classified under three divisions:—

1st. Those whose motive power is wholly electric, and which are wholly independent of any other force whatever.

2nd. Those depending on currents of electricity transmitted at regular intervals, and applied directly to carry forward the wheel-work and hands.

These two classes require no periodical winding-up, and may properly be termed electric clocks.

3rd. Those which, being complete clocks in themselves, and capable of performing all the duties of clocks without the external aid of electricity, show their own time, and require winding up at certain intervals, but, for the purpose of being made more useful and correct timekeepers, have currents of electricity transmitted from some standard clock, so applied as to control and correct the vibration of the pendulum or the movements of the wheel-work and hands, and so cause them to show uniformity of time with the governing clock.

Mr. Alexander Bain's electric magnetic pendulum was noticed, and high praise given to Mr. R. L. Jones's method for securing coincident time to the fraction of a second. Mr. Ritchie then described the electro sympathetic clocks introduced by his firm about five years ago, which are in use in many public offices, and have been exhibited at the South Kensington Exhibition of scientific instruments. The attention of the firm has recently been given to means of reproducing the most minute divisions of time, and the rest of the paper was devoted to their experience and success in accomplishing this end, with some indication of what has been done by others in the same field. Thus, about thirty-six years ago, the late Mr. Alexander Bain proposed a method of setting the minute hands of ordinary clocks to correct time every hour in a most simple and effective manner. Whether he ever put his system into actual operation, or to what extent, the lecturer had been unable to learn, but the plan is noticed in a pamphlet published in 1843, "On the Application of the Electric Fluid to the useful Arts," and is, fortunately, illustrated by a diagram and description with references. An electro-magnet was placed behind the dial of the clock to be corrected. The armature of the magnet carried a rod ending in a fork or V immediately above the figure XII. A pin projected back from the minute hand was so placed as to clear the arms of the V when the armature was at rest, or in its normal position, and forced to occupy the angle of the V, when, by the attraction of the magnet, the armature and rod were drawn upwards. Exactly at the last, or sixtieth second of the hour, as shown by the normal clock, contact was automatically made by it with a battery in connection with the line wire, so rendering the magnet active, and attracting the armature, and forcing the V against the pin in the hand, causing it to indicate the exact hour if within its range of action. The simplicity of this application must strike everyone, both from its direct action and fewness of mechanical parts.

To obviate defects found in Mr. Bain's method, Messrs. Ritchie substituted an I or block system, by removing one limb of the V and placing the other at a smaller angle to the pin on the hand, and giving the clock a slightly gaining rate. Instead of a momentary signal or current, one was adopted of fifteen seconds' duration, commencing at the fifty-ninth minute, forty-fifth second of each hour, and ending at the sixtieth second, or the exact hour of the normal clock. An automatic break is used where the line wire is passed by a spring, which is held out of contact with the battery terminal by means of a double lever, one end of which rests on the periphery of a disc upon the same axis as the minute hand. A notch in this disc allows the descent of the lever for a portion of a minute once an hour, during which the second lever comes into action on a disc on the scape wheel arbor. This has a stop cut away for one-fourth revolution to allow the lever to fall and contact to be made by the spring on the stud, commencing at the forty-fifth and ending at the sixtieth second, during which time a current is passed to the line.

The adoption of this system at once enabled Messrs. Ritchie to reduce the battery power, and to secure the hand more firmly to the clockwork, so that larger clocks could be placed in circuit and treated with safety. Further experience led to other slight modifications, and for the system is now claimed the following advantages over any previous methods of correction:—

1st. Extreme simplicity and lightness of the mechanical parts, and anyone conversant with electricity will at once appreciate how much depends on that.

2nd. The battery power required to work it is very small. This is obtained:—

(a) From the amount of motion in the stop pin being so small that the magnetic action on the armature is very powerful.

(b) No mechanical work is demanded of the current in setting the hands of the clock.

(c) No friction appears to be overcome, except that of the axis or centres on which the lever works.

(d) The preponderance of the double lever over the armature is just sufficient to ensure its falling out of action, consequently no power is wasted in doing unnecessary work or lifting useless weight.

The friction which (although it would prove very small) would be caused by the pressure of the scape wheel upon the stop pin is got rid of entirely by taking advantage of the inclined surface, or impulse part of the pallet, to wind back the wheel by the vibration of the pendulum, and allow the lever to fall freely out of action.

3rd. The certainty of action is very great, as the forward motion of the clock is arrested at the last wheel, or the point of greatest leverage in the train, and all uncertainties of elasticity are removed.

4th. The hands may be so securely fixed on that no exposure can affect them without wholly stopping the clock.

By no other method yet suggested could correction be applied to a large steeple clock, as any interference with the hands of such would result in the destruction of the apparatus or breaking the hands.

5th. The range of action is also very great. Should the clock be accidentally set slow of correct time, it will, by its own normal gaining rate, be accelerated till the hands indicate correct time, and only then will any action be performed by the corrector. Should the clock be set fast, even to the extent of five minutes (for the disc is cut to cover that extent of error) then the corrector could, by arresting the wheel work for the whole fifteen seconds in each hour, gradually eliminate the error, and have the clock set automatically to coincident time with the normal clock, and then resume its correcting action.

6th. It is applicable to clocks of all qualities and sizes, from the commonest German or American kitchen clock to the largest clock ever constructed, or which could be made or even conceived.

7th. The smallest possible expense in furnishing and fitting of apparatus and maintenance of battery power.

Elect News Sept 16. 75

Improvements in signalling or working signals on railways and in the means or apparatus employed therein. William Robert Sykes, telegraph engineer, Nunhead, Surrey. February 23, 1875. No. 662.—This Provisional Specification describes a novel system of signalling or of working signals whereby it becomes impossible for a signalman to give the signal for a train to proceed until he has received a signal from the next station or signalling point that the previous train has passed. The system is in fact a combined lock and block system, the movement of a signal lever for a train to proceed having the effect of locking that lever until the lock is released by the movement of a lever at the next station or signalling point after the train has passed it, while the lever at the said next station cannot be moved until freed by the movement of a lever at a third station or signalling point shewing that the line between the second and third points is clear.

165,700. *Electric Boiler-Alarms and Registers.* William C. Baker, New York, N.Y. Filed June 23, 1875.—Circuit closed by high or low pressure through magnets, controlling a dial and step-by-step escapement, thus registering how often the rules as to maximum and minimum of pressure have been violated. An intermediate magnet in same circuit closes branch circuit to self-acting magnetic bell. 1. The combination, with a low water or pressure alarm and an electric circuit-closing apparatus, of an electro-magnet, step-by-step movement, and dial, to indicate the number of times the boiler has been neglected, substantially as set forth. 2. The combination, with a boiler-alarm and electric circuits substantially as specified, of 6-branch circuit, electro-magnet alarm-bell, and automatic circuit-breaker, operated by the hammer, substantially as and for the purposes set forth.

Elect News Aug 19. 75

Improvements in the means and apparatus for indicating the speed of ships. Henry Edward Hargreaves, Rio de Janeiro, Brazil; at present of No. 12, Fenchurch Street, London. January 30, 1875.—No. 353. This invention relates to electric logs, wherein the revolutions of the vanes of the log cause an electric current to be passed at certain intervals along a conducting wire passing from the log to a recording instrument on board ship. According to the present improvements, the revolutions of the screw vanes effect the rotation of a worm and worm-wheel, on which is a stud that at every revolution of the wheel causes a contact-spring to close an electric circuit comprising a battery and a recording instrument on board ship. The recording instrument is an ordinary Morse receiving instrument, the paper strip being marked with divisions representing hours and minutes, so that the number of divisions occurring between two marks made on the paper by the passing of two consecutive currents will indicate the time in which the vessel traversed the distance corresponding to one revolution of the worm-wheel of the log.

Elect News Aug 26. 75

Electric Apparatus presented by M. Deschiens.—Report by Count du Moncel.—Some of these instruments are divided by M. Liais, Director of the Imperial Observatory of Brazil, viz:—(1.) *An Electro-Chronometric Regulator.* Without attempting a full description we may state that the interruptions of the current are effected under a bell jar filled with hydrogen, and on a mercury surface; thus obviating oxidation of the interrupter. The mechanical action working the interrupter and the pendulum is by a free escapement, which the pendulum only touches at each double oscillation just when passing the vertical. This escapement liberates a lever, solicited by a weight; which lever gives an impulsion to the pendulum, and also, before stopping, acts on a special beam, working the interrupter; the latter then causes an electro-magnet to be excited, which replaces the impelling lever in its former position and restores the escapement. The beam of the interrupter returns of itself to its normal position; so that everything is in position again for the next movement of the pendulum in the same direction. (2.) *An Electro-Chronometric Counter* (indicating on a dial the movements of the regulative pendulum).—To avoid the failure of contacts, M. Liais uses a massive pendulum, of annealed iron, acted on by an electro-magnet, so that if the contact should fail the dial train may not be affected; since the oscillation of the pendulum continuing all the same, the escapement always acts. Further, as the electro-magnetic action is only effective at the extreme points of the oscillations, the numerous contacts sometimes produced, resulting from certain trepidations of the apparatus, have no effect on the counter; as also the irregularities of velocity of the pendulum itself, which cannot quit the extreme point of its oscillation except when the current has ceased to pass through the electro-magnet. (3.) *Electric Chronograph.*—This is an improvement on one made by M. Liais twenty years ago for the Paris Observatory. The registration is not on a paper-covered cylinder, but on a paper sheet fixed on a horizontal circular plate; and the tracings are made in two spiral lines from circumference to centre. Thus a great number of indications can be made on one sheet, and the sheets can be easily kept in a portfolio. The cord of the motor is wound round a fusee, so that the turns of the plate may differ little from each other for the same interval of time. The two tracing styles are kept constantly pointed by the very fact of friction on the paper. The rotation of the plate turns a pulley, covered with a caoutchouc ring, which rests on it; and this turns two other pulleys with which the styles are connected, so that the latter are turned also in a continuous and regular manner. To obtain greater precision, copper points are sometimes used in place of the pencils, and the paper is prepared with zinc-white. (Some other improvements in detail are mentioned.) Among M. Deschien's own instruments is a system of dial telegraph, in which the regulation of the electro-magnetic action is effected in a double manner (by the tension of an antagonistic spring, and by the distance, greater or less, of the armature from the magnetic cores), by means of a double button placed in front of the apparatus, under the dial. This button corresponds to a hollow axis which envelopes a solid axis; the former has a helical groove in which catches a mother screw fitted to the antagonistic spring of the armature; the other, terminated by a screw, and worked exteriorly by means of a key which one introduces into the centre of the button, moves the iron of the electro-magnet, and the plate-form on which it is mounted. This arrangement is very convenient in practice.

L'Electricite July 20. 78.

Application de l'électricité à la photographie

On a remarqué qu'en électrisant positivement les plaques de verre dont se servent les photographes, le collodion se détache de lui-même. Nous reviendrons sur cette application aussi inattendue qu'intéressante.

Elect News Sept 16. 75 — 13/3

164,661. *Electrical Billiard Registers.*—Chas. H. Russell and Julius Sax, assignors to Bernhard Ahrens, all of London, England.—Two index fingers, one for each ball, carried on same shaft, one directly, one by a sleeve, each actuated by its own electro-magnet and circuit. First one around actuates mechanism scoring one game on the smaller or game dials. 1. The combination of the armature levers C C, the intermediate gearing a_1 a_3, and the index hands, substantially as described. 2. The combination of the armature levers, the intermediate gearing, and the index hands, with the game recording mechanism consisting, essentially, of the loose pulley M with its discs and stops, the intermediate gearing, and the recording dial and index, as described. 3. The combination of the pusher lever C, and the stop d_1 for limiting its backward movement, as described. 4. The combination of the pusher lever C, and the stop d^2 for limiting its forward movement, substantially as described. 5. The combination of the pusher lever C, and the stops d^1 d^2 for limiting its forward and backward movement. 6. The combination of the index hands a^1 a^2 and the gearing a^1 a^3, having the weight E, as described. 7. The combination of the studs N, the spring stops m^1, loose pinion M, and the connecting gearing, as described.

164,723. *Electric Toys.* Wm. Decker, New York.—Electrical excitation in the glass, resulting from rubbing, causes the figures to dance and execute various gymnastic feats. The electric toy composed of the glass plate A, which is supported on legs B, and of the rubber C, combined to affect the figures D D, which are placed beneath the glass, substantially in the manner herein shown and described.

L'Electricite Nov. 8. 78.

123174 : 13 mars 1878. — *Appareil électro-magnétique*, par M. F. Dumas.

Cet appareil se compose de deux organes essentiels :

1° Le *compositeur* ou *lecteur électro-musical* commande la production des sons en leur assignant la hauteur qui constitue la note musicale ; la durée, élément du rhythme ou de la cadence ; l'intensité qui donne l'expression, etc.

2° L'*exécutant électro-magnétique* qui a pour objet de remplacer les doigts de l'artiste en frappant ou pressant sur les touches du clavier ou sur les clés de l'instrument, soit directement, soit à l'aide de leviers, suivant les indications qui lui sont transmises par le premier organe.

123193 : 14 mars 1878. — *Compteurs électro-chronométriques*, par M. Tillet.

Le perfectionnement apporté à ces compteurs a pour but d'assurer la marche régulière des aiguilles, en supprimant les chocs produits par la brusquerie des mouvements des armatures et de permettre à ces compteurs de fonctionner avec des courants peu constants.

Sont supprimés : les répartiteurs, les ressorts à force antagoniste régulièrement croissante et les cliquets de retenu, etc.

L'avancement des aiguilles s'effectue un peu plus lentement en une seconde, demi-seconde ou quart de seconde, mais toujours sans choc.

L'Electricite Oct-20.78.

MÉTÉOROLOGIE ÉLECTRIQUE

—

M. Palmieri nous envoie une note sur la comparaison de l'électromètre à conducteur mobile et de l'électromètre à veine liquide descendante qu'il vient de présenter à l'Académie royale des Sciences physiques et mathématiques de Naples dont il est membre.

L'auteur se plaint avec quelque amertume que dans aucun traité français on ne parle de son appareil. En effet, nous ne le trouvons mentionné ni dans l'*Électricité* de M. Gavarret, ni dans l'*Électricité de tension* de M. Mascart.

Mais, quel est le plus à plaindre de M. Palmieri ou des plagiaires qui donnent ainsi une preuve évidente du peu de soin avec lequel ils se tiennent au courant des progrès de la science à laquelle ils prétendent initier leurs lecteurs?

L'auteur s'élève en outre contre une erreur qui paraît commune en France, et qui consiste à supposer que les électromètres prennent l'électricité des couches d'air avec lesquelles ils se trouvent en contact de la même manière qu'un baromètre indique la pression de l'air qui y règne.

Nous confessons que cette hérésie singulière est partagée par nombre de personnages officiels. Mais il est juste de faire remarquer que ces personnages ne sont, d'ordinaire, que des reflets des opinions allemandes. C'est à Berlin que se trouvent donc les personnes responsables de ces idées absurdes. C'est de l'autre côté du Rhin que M. Palmieri doit adresser ses doléances.

Il doit, jusqu'à ce que le public éclairé ait ouvert les yeux, se contenter de notre approbation sincère.

Nous demanderons la permission d'emprunter à l'excellent *Annuaire de l'Observatoire de Montsouris* pour 1878 (page 48) un passage qui montrera dans quelles conditions déplorables fonctionnent les électromètres Thompson de cet établissement modèle:

« Nous nous bornerons encore cette année à résumer dans deux tableaux les résultats tels qu'ils nous sont fournis par notre électromètre, depuis que le vase à écoulement d'eau a été placé à l'abri de l'humidité dans une des salles de l'Observatoire. Ces résultats sont faibles, parce que le filet d'eau qui se divise à un mètre quatre-vingts du sol et à un mètre du mur de l'Observatoire est dominé par le bâtiment qui, en ce point, a une assez grande hauteur et est en outre garni de deux balcons en saillie. Pour ramener ces nombres à ce qu'on eût obtenu à deux mètres du sol en plein gazon, *il faudrait les multiplier par un facteur voisin de sept en moyenne.* MAIS CE FACTEUR A ÉTÉ TROUVÉ TROP VARIABLE POUR QUE NOUS EN FASSIONS USAGE.

« Le 3 août, le potentiel moyen étant de 19,2 au niveau du filet d'eau, le potentiel de la couche d'air à deux mètres du sol, en plein gazon, a varié de 97 à 130 éléments Daniell dans le milieu du jour. Le lendemain 4, l'électromètre de l'Observatoire marquant en moyenne 15,2, nous avons obtenu, en plein gazon, des nombres variant de 72 à 111 éléments Daniell. Chaque fois que la vapeur d'une locomotive est chassée vers nous par le vent, les signes positifs font place à des signes négatifs très-accusés. *Une seule fois, le potentiel de l'air étant négatif nous l'avons vu passer, pendant quelques instants, au positif à la suite du passage d'une locomotive.* »

Nous ne croyons pas que M. Palmieri ait pu rédiger une critique plus mordante de l'appareil dont il combat si énergiquement et si savamment l'usage.

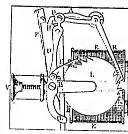
M. Palmieri craint que sa nationalité ne nuise au développement de ses doctrines. Nous nous bornerons à lui dire que la nation qui a produit Beccaria, Volta et Galvani sera toujours considérée, excepté par les Prussiens scientifiques de Paris, clique académique et universitaire dont l'influence tire à sa fin, comme étant la première des nations électriques.

L'Electricite Sept 20.78

Compteur électro-chronométrique. — Système de MM. Mildé.

Ceux qui sont venus visiter plusieurs fois l'exposition française de la classe 65 qui comprend, comme on le sait, tous les appareils télégraphiques, ont remarqué au fond de la salle un énorme cadran d'horloge qui depuis le commencement de l'Exposition a donné exactement l'heure sans se déranger, et qui n'a pourtant d'autre moteur qu'un tout petit mécanisme électro-magnétique mis en action par un simple pendule qu'on voit à l'exposition de M. Mildé. Pour ceux qui connaissent la marche capricieuse de ces sortes de compteurs, les résultats obtenus par ce système sont réellement très-intéressants, et ils feront peut-être revenir sur l'opinion si défavorable, qu'on a aujourd'hui, sur ce système de transmission de l'heure. Pourtant dans les mécanismes employés, il n'y a rien de réellement nouveau; mais la disposition de tous les organes est si bien entendue que c'est évidemment à elle qu'il faut attribuer les effets avantageux que ce système a fournis.

Nous représentons le mécanisme électro-magnétique du compteur. C'est, comme on le voit, un électro-aimant E E dont l'armature articulée oscille verticalement devant ses pôles en réagissant sur un levier articulé D qui porte le cliquet d'impulsion E et un butoir d'arrêt B qui empêche le passage de plusieurs dents au moment des impulsions. Le cliquet de retenue R articulé en S se termine par un bras muni d'un bec d'encliquetage qui joue au-dessus de l'extrémité supérieure de l'armature et peut l'encliqueter au moment où le bec du cliquet de retenue est soulevé pour laisser passer la dent. Or, il résulte de cette disposition que si le cliquet d'impulsion, après avoir poussé une dent, tendait à se relever avant que le cliquet de retenue n'ait fait son office, il en serait empêché par l'armature qui se trouve enclanchée jusqu'à ce que l'échappement soit



entièrement effectué. Celui-ci se trouve donc effectué indépendamment de la durée et des variations de l'action électrique et de l'action des courants d'air qui pourraient agir sur les aiguilles. Du moment où le rochet a commencé son mouvement, il faut qu'il s'accomplisse intégralement, le cliquet d'impulsion ne peut plus retourner en arrière, et comme le butoir d'arrêt empêche le rochet de faire sauter plus d'une dent en avant, celui-ci, au moment de chaque échappement, est retenu des deux côtés et est forcé de fonctionner régulièrement. D'un autre côté, comme l'armature réagit sur le levier D par l'effet de son articulation sur un point de sa longueur, qui peut être à telle distance que l'on veut du point d'articulation de D, on peut faire accomplir au rochet L la course nécessaire pour l'échappement de ses dents. Dans ce système, le ressort antagoniste de l'armature est constitué par une lame de ressort F dont on peut régler la tension au moyen d'une vis, et la distance attractive de l'armature est réglée au moyen de la vis à contre-écrou V.

La disposition de l'interrupteur appelé à faire fonctionner l'appareil précédent est aussi bien entendue. Pour ne rien changer aux conditions de l'horloge régulatrice, c'est l'ancre d'échappement lui-même qui constitue l'organe interrupteur. A cet effet, l'une des branches de cette ancre porte au-dessous de la palette de repos, et un peu en arrière, une petite palette de platine que peut rencontrer une cheville d'or placée sur la roue d'échappement, au moment où la dent correspondante à cette cheville vient appuyer sur la palette de l'ancre, il en résulte un contact par pression et par friction éminemment bon pour les effets électriques et qui n'exige pour se produire aucune force autre que celle nécessaire au fonctionnement de l'échappement lui-même, laquelle concourt par conséquent à l'entretien du mouvement du balancier au lieu de tendre à l'arrêter.

Pour assurer la bonté des contacts, M. Mildé, au lieu de faire ses liaisons électriques avec les pièces mobiles par des frotteurs, les effectue au moyen de longues lames flexibles dont l'une est fixée au guide du balancier près de son axe d'oscillation.

En somme, le système de M. Mildé, quoique ne présentant rien de nouveau comme principe, se fait remarquer par les bonnes conditions de sa disposition.

TH. DU MONCEL.

ELECTRICITY AS AN EXECUTIONER.—The revolting scenes accompanying the execution of criminals are well calculated to bring to public notice the disadvantages of hanging as a mode of capital punishment. Instead of building a gallows and providing rope, the sheriff, advised by a competent electrician, would procure a powerful Ruhmkorff coil and a heavy battery. These instruments would rarely need replacing, and would last indefinitely for other executions. The battery and coil should be of sufficient strength to deliver an eighteen inch spark. In case of there being more than one person to be executed, all of the condemned would be conducted with all due ceremony to the place of execution, the left hand of one man handcuffed to the right hand of his neighbour, and the conducting wire fastened to bracelets on the disengaged wrists of both criminals, if only two are to be hanged, or to the wrists of the outer men, if more than that number are to suffer. The culprits being seated so as to be seen by the legal witnesses, the sheriff presses a button. The current is instantly established from the coil, passes through the bodies of the men, and all is over. With a competent electrician, who might be a member of the police force, and specially charged with the duty, there would be no possibility of mistakes. The same ignominy which attaches to the gallows would be transferred to this mode of destruction, while the peculiar death by lightning, which, among the ignorant of all nations and ages, has been the subject of profound superstition, would, without doubt, through its very incomprehensibility and mystery imbue the uneducated masses with a deeper horror.—*Scientific American.*

Electric photometer.—Dr. Werner Siemens.—Crystalline selenium conducts electricity better when exposed to light than in darkness, the conductivity increasing directly with the degree of illumination. This property, which was discovered by Lieut. Sale, has been utilized by Dr. Siemens in the construction of a delicate photometer, the only additional apparatus required being a one cell Daniel battery and a galvanometer.

May 10 78

cérienne, cette tâche s'imposait comme une nécessité nationale. Aussi, le conseil municipal a-t-il donné l'impulsion que le Gouvernement et l'Assemblée nationale n'ont fait que suivre.

Le palais du bey de Tunis, épave laissée au Champ-de-Mars lors de l'Exposition universelle de 1867, sert à abriter un laboratoire où M. Marié-Davy a introduit un nombre incroyable d'intruments nouveaux et de dispositions ingénieuses, auxquelles personne n'avait songé. Il reste encore à résoudre pour la mise en activité régulière de ces opérations, une multitude de difficultés de détails et de problèmes inattendus.

Mais le zèle est si grand que l'observatoire de Montsouris sera un des objets les plus curieux de tout Paris, lorsque le Champ-de-Mars ouvrira de nouveau ses portes aux industriels et aux curieux accourus à l'envi des extrémités du monde.

Tous les services étant à créer, l'attention de M. Marié-Davy a dû se porter d'abord sur l'organisation des observations pour lesquelles les méthodes existent et les instruments ne sont point à inventer. Malgré son importance, l'électricité ne pouvait donc fixer dès les débuts l'attention du savant physicien, ses méthodes et instruments sont également à inventer.

On ignore même la portée et presque la nature des services qu'elle semble appelée à rendre. N'est-ce point à son propos que le mot d'Arago est vrai en toute rigueur, et que l'on peut écrire comme lui : « En science, l'imprévu a la part du lion. »

Cependant le rôle de l'électricité est déjà si important, que l'examen des instruments et outils électriques qui se trouvent à Montsouris offrira un grand intérêt de nouveauté. Que sera-ce quand on pourra se préoccuper de leur règlement et organisation systématique?

Nous partagerons cette étude rapide en trois parties : les paratonnerres, l'électricité ouvrière, et les instruments d'étude de l'électricité naturelle.

Depuis que M. Marié-Davy est directeur de l'observatoire, la foudre a déjà visité deux fois l'établissement. Avant que cette haute fonction ne lui fût confiée, elle avait déjà frappé le palais ; ce phénomène a été décrit par nous dans la *Liberté*.

Il était donc urgent de prendre des mesures contre de nouvelles invasions du fluide qui pouvaient être moins brusques que les précédentes, et sur lesquelles on pouvait compter, car la foudre n'ayant point de caprices, ces visites tiennent à quelque circonstance fatale.

Malheureusement la question des paratonnerres était en suspens, par suite de la création d'un comité spécial chargé de prendre des mesures pour assurer la parfaite efficacité de ces organes de protection. Il fallait donc attendre que le rapport fût déposé, et que l'adjudication ait eu lieu.

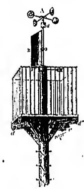
L'établissement de Montsouris sera un des premiers monuments publics pourvu de paratonnerres construits sur le système de la Commission, car M. Eugène Grenet, adjudicataire, a reçu toutes les instructions nécessaires pour procéder aux constructions et à la fabrication.

Les paratonnerres seront au nombre de trois, car chaque dôme est destiné à en recevoir un, comme on peut le voir sur la figure. Les pointes seules seront en cuivre, et les conducteurs en fer, la Commission n'ayant pu traiter l'observatoire différemment que les autres édifices municipaux. Le seul progrès saillant, réalisé dans la partie aérienne sera dans la suppression du platine, remplacé par un métal qui a le double avantage d'être moins dur et moins dispendieux. Les tiges seront, de plus, terminées par des pointes multiples recourbées, de manière à être en harmonie avec l'architecture générale du palais.

Mais, composée en grande partie de membres de l'Institut, la Commission ne croit chargée de travailler au progrès de la science électrique. Elle aura donc prochainement l'honneur d'installer le paratonnerre d'études de l'observatoire de Montsouris, car cet appareil sera indépendant, isolé de tout bâtiment, ne tenant aux autres paratonnerres que par le puits commun dans lequel se rendra son conducteur. Toutes les précautions seront prises pour que la conductibilité de cet appareil soit aussi parfaite que possible, et qu'il soutire par conséquent aux nuages des masses considérables d'électricité.

La partie souterraine pénétrera jusqu'à la nappe aquifère, et les communications seront établies de telle manière que l'action de l'humidité ne puisse jamais les détruire ou les affaiblir.

Les vérifications établies par la commission dans les autres édifices publics ont lieu deux fois par an. Il est clair que la commission ne saurait borner là son ambition, et qu'elle donnera certainement à l'observatoire de Montsouris *un tour de faveur!*



May 10 78

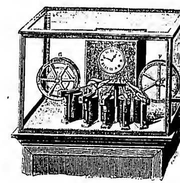
GIROUETTE DE L'ANÉMOMÈTRE ÉLECTRIQUE DE M. HERVÉ MANGON.

Si l'on suivait l'avis que nous avons exprimé dans notre brochure, sur l'*utilité d'établir le contrôle des paratonnerres*, on établirait certainement dans cette occasion le contrôle d'une façon permanente.

Nous arrivons en second lieu à l'étude de l'électricité ouvrière dont les emplois sont déjà nombreux et importants.

On s'en est servi dans la graduation de l'anémomètre enregistreur de M. Hervé-Mangon, dont nous donnons le dessin.

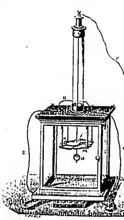
L'appareil se compose de deux parties distinctes. Au sommet d'un pilone, qui a 20 mètres d'élévation, se trouve une roue à coupe destinée à recevoir l'impulsion du vent.



ÉLECTRO-AIMANT ENREGISTREUR DES DIRECTIONS DE VENTS.

Les tours de roue sont enregistrés, *une marque* est faite tous les cinq cents tours par un électro-aimant sur un rouleau de papier mû proportionnellement au temps par un ressort d'horlogerie.

C'est ce renseignement que certains journaux publient chaque jour.



ÉLECTROMÈTRE THOMSON, MODIFIÉ PAR M. BRAULY.

La direction du vent est donnée par un procédé beaucoup plus compliqué, mais dans lequel l'électricité ne joue pas un moindre rôle.

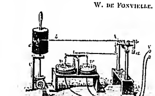
Quatre électro-aimants ont été affectés au service des quatre points cardinaux, se nommant : l'un l'électro-aimant du Nord, l'autre de l'Est, le troisième de l'Ouest et le quatrième du Sud.

Un courant est envoyé par un distributeur toutes les cinq minutes. Lorsque la girouette vient du Nord, c'est l'électro-aimant du Nord qui donne sa marque; lorsque le vent est entre Nord et Est, le courant passe à la fois dans les électros du Nord et de l'Est. Si la girouette remonte encore vers l'Est, c'est l'électro de l'Est qui, seul, est mis en action, ainsi de suite pour tout le rhumb.

L'électricité est parfaitement docile, mais elle ne joue dans ce système qu'un rôle très-subordonné, puisqu'elle se borne à produire l'ouverture et la fermeture des courants; son action ne se bornera pas toujours évidemment, dans la solution de cette question importante, à jouer un rôle si essentiellement secondaire. Nous demandons la permission de remettre à plus tard l'exposé de nos idées.

Il en sera de même des résultats obtenus avec l'électromètre de Thompson qui a été modifié par M. Brauly, et dont nous nous bornons à donner aujourd'hui la figure. La plus grande différence consiste comme il est facile de le voir dans la forme de la partie mobile. Quant aux dispositions qui sont prises pour assurer la conductibilité, elles sont analogues à celles qui ont été adoptées par le célèbre physicien anglais.

W. DE FONVIELLE.



précieuses adhésions, et les encouragements que nous avons reçus nous font espérer qu'il réunira dans une commune pensée, dégagée de toute influence hostile ou jalouse, tous les vrais amis de la science et du progrès.

HALLEZ D'ARROS

L'ÉLECTRICITÉ

A L'EXPOSITION UNIVERSELLE DE 1878

(9e *article*)

DE L'UNIFICATION DE L'HEURE DANS LES VILLES.

L'un des progrès qui est le plus réclamé aujourd'hui par l'opinion publique est l'unification de l'heure dans les villes. Quand on réfléchit aux conséquences que peut avoir pour les affaires une différence d'heure de quelques minutes, différence qui peut vous faire manquer un train de chemin de fer, une adjudication ou un rendez-vous d'affaires, qui peut vous rendre passible de punitions ou de réprimandes quand vous arrivez en retard, on se demande comment les villes n'ont pas plus tôt profité des nombreux moyens qui leur étaient offerts pour régulariser l'heure des horloges publiques. On répond, il est vrai, que l'écart des heures n'est jamais assez grand pour entraîner des dommages regrettables, mais j'ai constaté moi-même souvent des erreurs dépassant cinq et même dix minutes.

Les moyens proposés pour l'unification de l'heure sont de diverse nature. Les uns sont fondés sur l'emploi des effets pneumatiques, les autres sur les réactions électriques. Ces derniers sont évidemment les plus simples et les moins coûteux; mais les nombreux caprices de l'électricité se sont révélés si souvent dans les expériences que l'on a faites de ces systèmes, que la confiance que l'on pouvait avoir en eux s'est trouvée très-ébranlée. Ces résultats défavorables tenaient évidemment à ce que l'on n'avait pas appliqué l'électricité dans les conditions qui étaient spécialement propres à sa nature. Il ne faut pas perdre de vue, en effet, que l'on ne peut demander à l'électricité qu'une action mécanique très-minime; mais comme elle peut se manifester instantanément à telle distance que l'on veut, on peut en obtenir des effets que nuls autres moyens ne pourraient fournir et qui, combinés avec des actions mécaniques indépendantes, peuvent en devenir, en quelque sorte, l'âme ou la partie dirigeante. D'après ces considérations, il est évident que l'emploi des compteurs électro-chronométriques dans lesquels l'électricité fait tous les frais du mouvement, ne peut être recommandé pour l'unification de l'heure dans les villes; dans de grands établissements publics et industriels où les fils de communication ne sont pas sujets à être influencés par les causes extérieures, ils peuvent, il est vrai, être utilement employés à cause de leur bon marché relatif et de la facilité qu'ils donnent de faire fonctionner des cadrans de grand diamètre; mais du moment où ces fils doivent constituer des lignes aériennes ou même souterraines, leur emploi doit être proscrit, car ils ne peuvent présenter aucune sûreté dans leur marche. Il est vrai qu'avec les systèmes à courants renversés de M. Glœsener, les effets sont meilleurs, et plusieurs villes de la Belgique, entre autres Liége, ont un service public ainsi organisé, mais il faut qu'on y apporte une grande surveillance, et on m'a assuré que, souvent, l'on était obligé de réparer à la main les irrégularités d'action des mécanismes électro-magnétiques. Or, du moment où l'on est obligé d'avoir un service de surveillance, le système électrique devient une superfétation, car, en l'appliquant aux horloges ordinaires, on se trouverait avoir l'heure aussi exactement.

Ce que nous disons des compteurs électro-chronométriques dans lesquels l'électricité fait tous les frais du mouvement peut également s'appliquer aux compteurs électro-chronométriques à mouvements d'horlogerie dans lesquels la marche des aiguilles dépend d'échappements déterminés électriquement. Sans doute, l'action électro-magnétique est alors plus sûre, mais les effets des courants accidentels ne sont pas prévenus pour cela, et il peut alors se faire que des échappements soient effectués en dehors de la transmission ou manquent tout à fait, et, comme avec ce système les erreurs s'accumulent, il peut se faire qu'au bout de plusieurs jours on ait à enregistrer des retards ou des avances sensibles. Il faut, de plus, remonter les horloges comme si l'électricité n'intervenait pas.

Ces différentes considérations ont fait penser à la commission des horloges de la Ville de Paris que l'unification de l'heure dans une ville n'aurait quelque chance de succès qu'en n'employant l'électricité que comme un moyen auxiliaire, c'est-à-dire comme un organe de sécurité et de correction dont l'intervention pourrait ne pas être indispensable à la marche des horloges, mais qui, lorsqu'il réagirait, pourrait en corriger les défectuosités à des intervalles de temps plus ou moins éloignés. D'après ce principe, il était indiqué qu'on devait toujours employer pour les horloges publiques des horloges ordinaires, mais qu'on devait leur appliquer un mécanisme correcteur qui pouvait être plus ou moins compliqué suivant la précision qu'on voulait apporter à leurs indications.

Le problème, posé de cette manière, est évidemment susceptible de plusieurs solutions. On peut, en effet, demander à ce mécanisme correcteur une action toutes les secondes, et alors le problème se trouve ramené à synchroniser électriquement les oscillations du balancier des diverses horloges à régler d'après celles du pendule d'une horloge type ou régulatrice. Ce système permet d'unifier l'heure à une très-petite fraction de seconde près; mais, en somme, une pareille précision, utile il est vrai pour les horlogers, n'est pas nécessaire pour le public qui se contenterait d'avoir l'heure à quelques secondes près; et si on réduit le problème à ces dernières conditions, sa solution devient beaucoup plus simple et plus facile, car il suffit de remettre à l'heure électriquement les horloges, soit toutes les heures, soit même une fois par jour. Il faudrait, en effet, qu'une horloge fût bien mauvaise pour varier d'un certain nombre de secondes dans l'espace d'une heure. Dans une ville peu considérable, il est évident que le problème posé de cette manière satisferait aux besoins des populations, et nous verrons que les essais qui ont été tentés peuvent donner raison à cette conclusion; mais dans une grande ville comme Paris, il n'en est plus de même. L'heure exacte peut être donnée par l'Observatoire, et il est utile pour le réglage de tous les chronomètres qui s'y construisent, que les horlogers puissent avoir l'heure exacte dans leur quartier, sans qu'ils aient à se déranger pour la prendre chaque jour à l'Observatoire.

On pouvait donc désirer que, dans les différents quartiers de Paris, il y eût des centres horaires dont les horloges pussent marcher complétement synchroniquement avec celle de l'Observatoire, et qui pussent à leur tour servir d'horloges régulatrices pour remettre à l'heure les différentes horloges de leurs quartiers respectifs par des moyens plus simples. C'est ce dernier parti qu'a adopté en principe la sous-commission des horloges de Paris, et elle en étudie actuellement les moyens d'exécution.

Sans préjuger en rien les décisions qui pourront être émises par cette commission et celles du conseil municipal de la Ville de Paris, nous pouvons donner une idée de la manière dont le double problème pourrait être le plus facilement et le plus complétement résolu.

On pourrait, par exemple, établir au centre de la Ville de Paris un double réseau télégraphique partant de l'Observatoire, pour constituer deux circuits entièrement métalliques et indépendants, comprenant chacun six centres horaires que l'on choisirait de manière à être échelonnés circulairement, l'un à l'est, l'autre à l'ouest de la Ville de Paris. Par ce moyen, chaque circuit n'aurait qu'un fil, et ce fil serait utilisé dans toute sa longueur, depuis son départ de l'Observatoire, où il rencontrerait les centres horaires du centre de Paris, jusqu'à son retour à l'Observatoire où il n'arriverait qu'après avoir desservi les centres locaux échelonnés dans les parties excentriques de la capitale. Nous verrons à l'instant que le dispositif mécanique des horloges disposées à cet effet se prête admirablement à cette combinaison.

De cette manière, la Ville de Paris aurait donc douze centres horaires d'où on pourrait ensuite distribuer l'heure dans les quartiers avoisinants, au moyen de réseaux télégraphiques particuliers qui viendraient y rayonner et dont la disposition serait plus ou moins compliquée, suivant le système de remise à l'heure adopté.

Il s'agit maintenant d'examiner comment le double problème que nous venons de poser pourrait être résolu au point de vue des instruments chronométriques. A ce point de vue, la question n'est pas embarrassante, car deux systèmes qu'on pourrait dès maintenant adopter ont été expérimentés depuis assez longtemps pour qu'on soit certain de leur réussite. Depuis trois ans, en effet, les nombreuses expériences faites entre l'Observatoire et le Conservatoire des Arts et Métiers ont montré que l'on pouvait obtenir le synchronisme parfait de marche de plusieurs horloges en régularisant électriquement les oscillations de leur pendule par le système de MM. Foucault et Vérité, et l'on a pu reconnaître par les essais faits au lycée Fontanes, à la Mairie du IVe arrondissement et à Roubaix, que le système de remise à l'heure de M. Collin pouvait amplement satisfaire aux besoins du public. Nous allons donc entrer dans quelques détails sur ces ingénieux systèmes que l'on peut du reste étudier à loisir à l'Exposition, car l'un, le premier, est adapté à l'une des horloges exposées dans le pavillon de la Ville de Paris, qu'elle est réglée toutes les secondes par l'horloge de l'Observatoire, et le second est appliqué à la grande horloge que l'on remarque en avant de l'exposition de M. Collin, et qui règle un certain nombre d'horloges des kiosques.

Système de réglage des horloges de MM. Foucault et Vérité. — Ce système, imaginé dès l'année 1847 par M. Foucault, et rendu pratique en 1863 par M. Vérité, est basé sur l'action d'un ou de deux électro-aimants placés au-dessous du balancier de l'horloge à régler au point où ce balancier atteint ses écarts extrêmes, et qui actionnent une armature de fer doux, fixée à la partie inférieure de ce balancier. De cette manière, si celui-ci atteint un de ses écarts extrêmes un peu plus tôt qu'il ne doit le faire pour correspondre à l'oscillation correspondante du balancier de l'horloge régulatrice, il se trouve retenu dans cette position jusqu'à ce que le balancier régulateur ait atteint la même position, et ce n'est que quand cette coïncidence de position se produit, qu'un interrupteur adapté à l'horloge régulatrice coupe le courant et permet aux deux balanciers de partir ensemble pour accomplir leur oscillation rétrograde. Les mêmes effets se renouvelant incessamment pour chaque demi-oscillation des balanciers, ceux-ci sont forcés de marcher synchroniquement, et, par conséquent, de fournir l'heure exacte. Il faut seulement que les horloges à régler aient une petite avance sur l'horloge régulatrice, ce qu'il est toujours facile d'obtenir.

Une des parties les plus délicates de ce système a été l'interrupteur de l'horloge régulatrice, et, sous ce rapport, M. Breguet a perfectionné considérablement le système primitif. Dans ses conditions actuelles, il se compose de six leviers articulés (trois de chaque côté du pendule de l'horloge régulatrice), disposés de manière à recevoir à chaque oscillation du pendule le contact d'un frotteur à trois lames qui établit une triple communication métallique entre la pile et le circuit à chaque inclinaison du pendule, à gauche ou à droite de la verticale. Ce frotteur est adapté à l'extrémité supérieure du pendule, et si près du centre d'oscillation, que l'influence qu'il peut exercer sur la marche de l'horloge est très-minime. Nous allons voir d'ailleurs que, dans ce système, la marche de l'horloge régulatrice doit être corrigée tous les matins par l'astronome chargé de ce service à l'Observatoire.

L'expérience a montré qu'un seul des systèmes d'interrupteurs dont nous venons de parler était suffisant pour régulariser la marche des horloges à régler et que l'on pouvait introduire dans le circuit tel nombre d'horloges qu'il pouvait convenir, pourvu qu'on augmentât la pile proportionnellement. On peut en conséquence faire réagir les deux systèmes d'interrupteurs sur les deux circuits dont nous avons parlé et en introduisant dans chacun d'eux six horloges, on ne dépasse pas les limites de résistance susceptibles d'être vaincues par une action électrique modérée.

Les avantages de ce système d'interrupteur sont faciles à comprendre; d'abord, les oxydations dues aux interruptions du courant, se trouvant réparties sur trois points, sont moins fortes; en second lieu, si l'un des contacts manque par suite de circonstances accidentelles, les deux autres sont là pour le suppléer; en troisième lieu, on peut nettoyer facilement et successivement ces contacts sans altérer

THE TELEGRAPHIC JOURNAL.
Vol. I.—No. 17.

DR. C. W. SIEMENS'S ELECTRICAL PYROMETER.

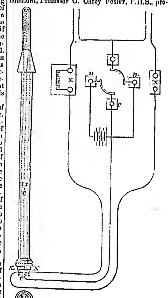
The electrical resistance of metal conductors depends upon their dimensions, material, and upon their temperature; an increase of the latter causing a corresponding increase of resistance. The law of this increase is known. Thus, the resistance of a conductor being ascertained at 0° C., it can be calculated for any temperature, and, *vice versâ*, if the resistance can be found by measurement, the temperature can be calculated. This is the principle upon which the Electrical Pyrometer is based.

A platinum coil of a known resistance at 0° C. is coiled on a cylinder of fire-clay, protected by an iron or platinum tube, and is exposed to the temperature to be determined. Leading wires are arranged to connect this coil with an instrument suitable for measuring its resistance, and from this resistance the temperature can be calculated.

The instrument supplied for the purpose of measuring the resistance is a differential voltameter. The Differential Voltameter consists of two separate glass tubes, in each of which a mixture of sulphuric acid and water is decomposed by an electrical current passing between two platinum electrodes. The gas which is generated is collected in the long cylindrical and carefully-calibred top of the tube, and its quantity is read off by means of a graduated scale fixed behind the tubes. Movable reservoirs are provided, communicating with the tubes, to regulate the level of the liquid. The current of the battery is divided (by passing a commutator) into two circuits, one of which consists of an artificial resistance in the instrument and the platinum electrodes in one tube; the other, of the resistance to be measured and the electrodes in the other tube. The quantities of gas developed in the two tubes are in inverse proportion to the resistances of their respective circuits, therefore one of the resistances, viz., that in the instrument, being known, the other can be calculated.

When required for use, the battery glasses are filled with pure water, or, in case of the power of the battery decreasing, with a solution of sal-ammoniac in water. The poles are connected to n and n' on the commutator. The small end of the tube, as far as the cone, is exposed to the heat to be measured, and the terminals x, x', c are connected to the ends of the leading cable bearing corresponding letters, and the other end of the leading cable to the terminals x, x', c on the voltameter. The differential voltameter is filled with the diluted sulphuric acid through the reservoirs, the india-rubber cushions being lifted from the top of the tubes. The commutator is then turned so that the contact springs on both sides rest on the ebonite. The liquid in both tubes is regulated to the same level (0° of scale), and the india-rubber cushions let down again. When the commutator is turned through a quarter of a circle on to the brass, the development of gas will commence almost immediately. The commutator should be turned half round every ten seconds to reverse the current. The current is kept passing until the liquid has fallen in the tubes to at least 50° of the scale, then put in its first position, so that the contact springs rest on the ebonite; the level of the liquids is read off on the scale, these numbers found in the table accompanying the instrument, and the intersecting point of the lines starting from these figures gives the resistance of the exposed coil in black, and its temperature in red, figures. For a new experiment the levels are adjusted as before.

At a recent meeting of the British Association, at Bradford, Professor G. Carey Foster, F.R.S., pre-



sented to the Chemical Science Section the report of the Committee appointed by the Association to examine and report upon the merits of the pyrometer; and the report stated that the first step was evidently to test the electrical permanence of the pyrometer, and the attention of the committee has as yet been confined to the examination of this point. At the Brighton Meeting in 1872, it was reported by them that a pyrometer whose resistance was, to begin with, 9·917 B. A. units at 10° C., had a resistance of 10·502 at the same temperature, after having been repeatedly heated to redness. This change was found by Professor Williamson to be, in all probability, due to chemical alteration of

---

21

means and by the ... needle instrument.

Prof. Palmieri has discovered a new instrument which he calls the "dingumeter," and which is constructed for the rapid examination of oils and textures by means of electricity. What the apparatus will do Prof. Palmieri details thus: 1. It will show the quality of olive oil. 2. It will distinguish olive oil from seed oil. 3. It will indicate whether olive oil, although of the best appearance, has been mixed with seed oil. 4. It will show the quality of seed oils. 5. Finally, it will indicate the presence of cotton in silken or woollen textures. The professor has been complimented for this invention by the Chamber of Arts and Commerce at Naples, who have published a full description of the apparatus, with instructions for use.—(*Nature.*)

In an amusing article on "Insular Egotism" the *New York Telegrapher* gravely publishes the following interesting information:—In no other country has telegraphy acquired such perfection in actual use or been so universally adopted and used by the people as in the United States and Canadas. More actual business is transmitted daily on a single circuit by two operatars in this country than by four operators on

Electric Chronographs.—By Marcel Deprez.—In every chronograph there are three distinct kinds of organisms:—(1) to print the movement of the projectile on paper; (2) registers to leave a trace on the paper at the moment when the body passes certain determined marking points; (3) a registering apparatus of equal intervals of time. Called upon to make a deep study of these machines in order to render them reliable registers, he used one of Schultz's chronographs, one of the features of which is rapid vibrations of a tuning-fork. The registering of the successive moments of the phenomenon to be studied was made by means of the induction spark. M. Marcel Deprez first determined the delay of the spark, *i.e.*, the time interval which passes between breakage of the inducting current and the spark's explosion, by causing the chronograph's own cylinder, which carried an insulated sector, to break the circuit. He commenced by turning the cylinder very slowly, when a certain mark was obtained at the moment in which the insulating sector broke the inducing current; then, spinning it round with great swiftness, a new mark was obtained, produced by the spark which struck the cylinder during this rapid movement. All the results of his experiments cannot be given; suffice it to say they showed that of all registering processes the induction spark is by far the most rapid, the *delay* being generally below $\frac{1}{18000}$th of a second. Certain serious inconveniences render its employment almost inadmissible. Indeed its production is very capricious, and much depends on the manner in which the inducing current is broken. It almost always strikes the cylinder at a great number of points, when it leaves a mark like a comet with a tail composed of sparks. When the speed of the cylinder is very great the mark becomes extremely uncertain. Notwithstanding all these inconveniences, it is perhaps preferable to other methods of registering by reason of its instantaneousness, provided, with a single coil, an extremely large number of sparks can be produced in a second. Unfortunately we cannot do so. The number of sparks produceable in a second do not exceed two or three hundred, and then only with a strong battery and a very small explosive distance. As to the use of electro-chemical paper very little is to be said: it has been abandoned because the mark presents a very uncertain ending. Lastly, electro-magnets appeared utterly inadmissible under the circumstances in which he was placed.

ELONGATION OF CONDUCTORS BY ELECTRICITY.—Various physicists have from time to time studied the modifications in the molecular state of the conducting wires, due to the passage of the electric current. Wertheim arrived at the conclusion that the transmission of the current modified the elasticity of the conductor, but Edlund, on the contrary, by a series of careful experiments, has determined such not to be the case. This latter investigator has found, however, that the elongation of the wire under the influence of the current is sensibly greater than the dilatation due to the elevation of temperature resulting from the passage of the electricity. Two calculations were made of the temperature of the wire, one deduced from the relation previously established between the galvanic resistance of the conductor and its temperature, the other from the elongation of the wire directly measured and of its coefficient of dilatation, equally known. The second mode of determining the temperature constantly gave higher figures than the first, and M. Edlund therefore concluded that the current produced a special elongation in the conducting wire which is added to the expansion resulting from the accession of heat.

Quite recently M. Streintz has taken up this subject, and, by further investigation, has sought to measure accurately the galvanic elongation for different metals.

The observations were made on wires 0·019 inch in diameter and 21 inches in length, the ends of which just touched two levers which carried mirrors placed in the prolongation of their axis of rotation. The divisions of a graduated scale were reflected in the mirrors, and thus the displacement of the extremities of the wires could be accurately read. All the wires, except those of hard tempered steel, showed a marked excess of expansion under the action of the current, which varied according to the different metals, from 11 to 27 per cent. of the dilatation of the wire under the action of heat alone when brought from the normal temperature, 68° Fah., to that fixed as a limit, 131.4°.

M. Streintz sums up his results as follows: 1. The galvanic current causes no other modification of the elasticity of a conducting wire than such as results from the elevation of the temperature produced.

2. Under the action of the current, the conductor expands more than when it is carried to the same temperature without the current; tempered steel alone does not present this excess of dilatation.

3. Galvanic dilatation does not manifest itself immediately on the closing of the current, but gradually, as does calorific expansion.

4. Galvanic dilatation is not the consequence of an electrodynamic repulsion, but probably results from a calorific polarization, or an orientation of the calorific vibrations.

Gas Lighting Apparatus.

This patent was granted to Adolph T. Smith, of New York city, March 10, 1874.

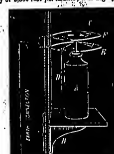
This invention is highly ingenious. It is not a telegraphic gas lighting device, but is designed to supplant matches or replace the "electric torch" of Batcheller, to which it is apparently superior.

The device is shown in fig. 2. X is the body of the burner which is made of soft iron; surrounding this is a bobbin, M. G is a vibrating contact spring secured to the bottom of the bobbin M and provided with a small armature P. The spring is extended up over the burner and made to face a rigid point, N, secured to the burner. These points are tipped with platina and are shown over the jet in the diagram in order to understand the principle clearly.

An Electric Toy.

To the Editor of the Scientific American:

I send you herewith a sketch of a scientific toy, which I have recently constructed and placed on a bracket in front of the desk in my engine room. The main belt of the engine is 30 inches in width, and about 120 feet in length, and runs from south to north, at an angle of about 45°, and with a velocity of 2,500 feet per minute. It is highly electrical.



The idea occurred to me that the electricity so developed might be made use of for mechanical or other purposes; and having seen an engraving of what is called an electrical wheel, I constructed one as shown herewith, but without the coils. A is a vial, about 6 inches in length by 1¼ inches in diameter, the bottom of which is inserted in a cavity in the bracket, B. In the center of the cork is inserted the eye end of a darning needle, the point projecting upward about 2 inches, on which rests the wheel, C, which consists of two pieces of copper wire, 1-32 inch in diameter and 7 inches in length, placed at right angles to each other; their centers are flattened and soldered together, and half an inch of the end of each arm is bent at a right angle, all in the same direction, and filed to a point. D is a copper wire, one eighth inch in diameter, one end of which rests against the needle, the other running in front of and about 6 inches distance from the belt, and terminating in 5 or 6 points, 2 inches long, projecting toward it.

On connecting the conducting wire with the needle, my wheel immediately started off at a speed of 100 turns in 50 seconds. I soon ascertained that, by placing a good metallic conductor beneath the wheel and making an earth connection, I could add materially to its speed. Accordingly I placed a copper coil, E, 5¼ inches in diameter, one inch below the wheel, connecting it with the gas pipe, which accelerated its speed to 148 turns in 50 seconds. Soon my wheel began to gyrate even to an angle of 20°. This annoyed and puzzled me. I eventually found that, by adding another coil, F, one inch above the wheel, and connecting it with the earth, I not only restored its equilibrium, but also increased its velocity to 173 turns in 50 seconds.

When the air is dry and frosty, I have had it running as fast as 280 turns per minute, and the ozone given off by the wheel is apparent to the senses at a distance of several feet. It also acts as a barometer, indicating (by increasing or diminishing its speed) atmospheric changes several hours in advance. It is especially lively on the approach and during the prevalence of a northeast snow storm; but with the wind anywhere from east to south, it will scarcely move at all.

The apparatus can be easily constructed by any person of ordinary intelligence, and it makes a very interesting scientific apparatus. It can as well be located in the counting room or office as in the engine room.

328 Delancy street, New York city. EDWIN LEACH.

New Electromagnetic Station Indicator.

Mr. Charles W. White, of New York city, has patented, August 18, 1874, through the Scientific American Patent Agency, a quite ingenious station indicator, by means of which the names of places printed on an endless band are caused to appear and change by the action of mechanism, controlled by electromagnets. The rollers over which the band passes are geared to each other, and are rotated by a spur wheel, which is itself turned by a ratchet in which a pawl engages. The latter connects with levers vibrated by the movements of the magnet armatures, so as to cause the pawl to turn the ratchet, and so cause the band to move around the rollers. There are two sets of this gearing, in order that the band may be turned in either direction. In addition to this, there is a check pawl, which is lifted when the carrying pawl is operated. This locks a ratchet, so that the band is firmly held at any point until again set in motion by the mechanism. The indicators are placed in any convenient position in the cars, and from each set of magnets an independent circuit is led to the point whence the machine is to be controlled, where a suitable closer is placed in each circuit. Upon one circuit being closed, the indicating ribbon is unwound from the top roll, and wound on the lower one; the other circuit established, the reverse takes place.

The mode of locking the mechanism and the ratchet arrangement for turning the rolls are novel, and embrace efficient improvements in the electromagnetic principle for operating station indicators.

attainable would be that afforded by the use of a system of working so organised that an accident could occur without the simultaneous misconduct of all three of those parties; but practically no such system can exist. It is, however, quite possible to use a system in which an accident can only be caused by the simultaneous misconduct or neglect of two out of the three parties, and in our opinion no system which affords a less security than this should ever be employed to control the traffic on single lines. To obtain this twofold security it is essential that the driver and guard in charge of a train which is about to traverse a single line should, before starting, be furnished with absolute evidence that the station-master or inspector, from whom they receive the starting order, has for the time being the length of single line at his disposal. When the "staff" system is employed, this evidence is afforded by the "staff," which must either be handed to the driver or shown to him if he is despatched by ticket.* It is the duty of the driver to see the staff before starting, and, except by the simultaneous misconduct of the driver and the station-master or inspector, it is thus impossible that where the staff system is in use a train shall be sent off from a station which, for the time being, has not the line at its disposal. If, on the other hand, the line be worked by telegraph, then as we urged in our number of the week before last, printing telegraphs should be used, and a driver should only start when he has had handed to him a printed message received from the station towards which he is going. This message would be an assurance to the driver that the inspector from whom he received his starting order had for the time the control of the line, and that the station-master or inspector at the other end knew he was coming. When once a train was despatched no other train could be despatched in an opposite direction to meet it without the concurrent misconduct of the officials at both ends of the line. As we stated in our former article when explaining this system more fully, the great point lies in the driver not receiving a mere verbal starting order and not acting solely on the authority of the station-master or inspector by whom he is started. In other words it is essential, as we have said, that the driver should have substantial proof that the officials at the other end of the line know that until his arrival at their station they have no authority to despatch a train. Of course there is one contingency which no system can entirely guard against, and that is the chance of a driver starting without authority. This contingency is, however, an exceedingly remote one, and even it can be partially guarded against by making it incumbent upon the guard of a train to receive the same authority to proceed as the driver.

In his summing up to which we have referred, and which has no doubt been perused by most of our readers in the columns of the daily press, Captain Tyler appears to take a somewhat favourable view of the system of control in force between Norwich and Brundall, and the system has certainly one great point in its favour, namely, that it had worked for many years without mishap. It had, however, as we have shown, the serious defect that the misconduct or carelessness of one person could upset its security, whereas it is possible by the adoption of other systems to insure immunity from accident unless two persons concur in their misconduct—an arrangement which gives far more than twofold security.

TORPEDO EXPERIMENTS.

SINCE our last notice of the torpedo experiments against the hull of the Oberon, two more—the third and fourth of the present series—have been carried out, and the vessel still remains whole—we can hardly say intact. The results of the last experiment, however, render it very questionable whether she would not have succumbed to the force of the explosion had her inertia been that due to a vessel of her size fitted with engines and boilers, and fully armed and equipped, instead of that presented by a mere empty hull. The third experiment took place on the 5th of September last, and was carried out under precisely similar conditions to those by which it had been preceded, with the exception that the distance between the torpedo and the vessel had been decreased by 20 ft., the distances being in the first experiment 100 ft., in the second 80 ft., and in the third 60 ft. The torpedo was an iron case containing 500 lb. of Waltham Abbey disc gun-cotton, saturated with fresh water, and fired by dry discs electrically exploded. The Oberon was provided with crusher gauges as before, arranged as described and illustrated at page 126 of our present volume. The torpedo was exploded about four o'clock in the afternoon, the firing party being stationed at Fort Monckton. The usual upheaval of water followed the explosion, the effect of the latter being perceptibly felt on board the various vessels lying off the Oberon. An internal examination of the vessel after the explosion disclosed the fact that the hatchway combing had been unshipped, and the water tanks displaced as before. The live stock placed on board, and which consisted of sheep and rabbits, again escaped without injury. An examination of the bottom of the Oberon after she had been placed in dock showed that although no appreciable damage had been done to it, still the limits of safety were being very closely approached. It was, therefore, determined that for the fourth experiment the distance should only be decreased by 10 ft. instead of 20 ft. as in the last case.

As it was not improbable that the next torpedo might decide the fate of the Oberon, it was resolved to adopt such measures as would enable her to be kept afloat and towed into dock with the least possible delay should she become disabled. To this end a large quantity of iron ballast was taken out of her, and an equivalent weight in the shape of water tanks and casks stowed away in her. Most of the tanks and casks were empty, but it was necessary to fill some of them with water in order to supply the weight required above that afforded by the tanks themselves to bring the Oberon down to her proper draught. Heavy baulks of timber were set up between the paddle-box outer beams and the upper edge of the outer bottom clear of her sides, in order to afford a hold for the lifting chains. The chain cables with which the Oberon has been provided for holding her together in the event of her hull being fractured by the mine, or for enabling her to be raised, either wholly or in parts, should she be sunk, were disposed in four double loops extending over each side and round the bottom of the vessel. She had also a double length of chains placed in line with her keel connected with the transverse loops, and made fast inboard over each bow and quarter. In order further to provide for her being raised from the bottom should such a necessity arise, two vessels—the Laurel, an old sailing frigate, and the Rinaldo, a useless screw sloop—were prepared for the purpose of being used as a floating lifting power. The other precautionary measures consisted in placing ships' hand pumps in the hatchways wherever they could be worked, supplemented by ships' fire engines to keep the vessel clear of water should a breach be effected. Beyond all this was a very sensible and sailor-like arrangement, suggested by Captain Moriarty, for stopping to some extent any leak. This consisted in making fast an old sail to the bulwarks directly over the area upon which the full force of the explosion would be exerted. The sail was furled and secured by slight rope-yarn stops to the topsides, the lower edge of the sail being weighted, so that when let go it would rapidly sink and cover the fracture caused by the torpedo.

These preparations occupied some time, and caused the fourth experiment to be delayed somewhat beyond the time originally named for it to take place. Ultimately, however, it was arranged that the torpedo should be fired at 9 o'clock on Saturday last, and this programme was carried out. In addition, however, to the arrangements we have mentioned, there were others which had reference to the probability of one torpedo exploding another in its vicinity. This question has been suggested in a very practical manner by the results of a series of experiments similar to our own, which are being carried out at the present time by the Swedish Government against a similar vessel to the Oberon. The difference, however, consists in the explosive used as a charge, the Swedish experiment being carried out with dynamite, and the English with gun-cotton. The Swedish experiments have proved that a primary torpedo charged with 150 lb. of dynamite and fired, exploded by concussion two other similar charges, each laid 200 ft. away from the primary torpedo and unconnected with it or with each other. In order to ascertain the action of gun-cotton under similar conditions in the experiments of last Saturday, a secondary charge of 100 lb. of Waltham Abbey disc gun-cotton saturated with about 30 per cent. of fresh water, was placed in a service mine case, and laid about 120 ft. diagonally away from the main torpedo. Another secondary charge, consisting of 50 lb. of gun-cotton, was secured in a piece of netting, and placed 120 ft. in another direction from the primary charge. The two secondary torpedoes were placed on a bed of soft sand at a distance of 100 ft. apart, and were held down by iron ballast. All being ready, and the Oberon being surrounded at a safe distance by the usual complement of Admiralty and other vessels, the torpedo was fired at a few minutes after 9 A.M. from Fort Monckton. The water was upheaved as on previous occasions, the outer mass catching the Oberon under her starboard side, raising her, and causing her to roll heavily for some minutes. To all appearance, she had sprung a bad leak, and was settling down. She was quickly boarded by dockyard hands, who were in attendance for the purpose, and her pumps and fire engines were manned, and the sail-cloth fracture stopper was dropped. Her cables were then shipped, and she was once more towed into dock by a couple of tugs. On the way, however, it soon became evident that there was no serious leak, and therefore no internal fracture, as the ship was quickly pumped dry, the only water she had contained being that which she had shipped from the column thrown up by the explosion.

An external examination of the Oberon, made in dry dock, soon disclosed the fact that a very marked impression had been made on her outer skin by the explosion of the torpedo. The pressure brought upon the plating had buckled it to a considerable extent, so that the longitudinal and vertical framing between the inner and outer skins stood out in bold relief. The chief seat of weakness is, of course, the region around the condenser inlet and outlet pipes, and there a number of rivets were found to have been started, the mouth of the outlet pipe was split, and the sea connexions of the condenser more or less damaged. What the results would have been if the Oberon had presented 9000 tons of inertia to the blow, as would the Hercules, instead of only 1000 tons, may be pretty well imagined. It would hardly have been possible for her to have survived the shock of the explosion. At the best, her powers of flotation would not have remained unimpaired, as they now are, and with full boilers, and her machinery in motion, she would in all probability have at once gone to the bottom. The animals on board were not hurt, but were thrown down, as they had been in every previous experiment. The water tanks were not removed, owing to extra precautions having been taken in securing them well in place with heavy timbers.

We should mention that neither of the secondary charges were fired by the explosion of the primary charge of 500 lb. of gun-cotton in the torpedo. This circumstance is due to the fact that all three charges were more or less embedded in the mud on the bottom of Stokes Bay, whilst the explosion of the Swedish secondary charges is explained by their having been—together with the primary charges—suspended 10 ft. from the surface of the water. The fifth of the Oberon experiments will probably take place in another week or so, when the distance between the torpedo and the Oberon will probably be reduced to 40 ft. The secondary charges will most likely be placed 120 ft. from the primary charge and from each other, and they will consist of wet gun-cotton discs with dry priming discs, so as to represent correctly the conditions of actual practice. The experiments with these secondary charges are being carried out by the Torpedo Committee, who, although distinct from the Oberon Committee, yet act in concert with its members.

THE CORPORATION AND THE CITY GAS SUPPLY.

IN our issue of August 28th we gave full particulars of the proposed action of the Metropolitan Board of Works, in reference to the gas supply of London exterior to the boundary of the City proper. After reciting all that had been done by the Board to ameliorate the existing state of things due to the monopoly now possessed by the nine London gas companies, it was stated that the Board had resolved to apply to Parliament during the next session for an Act to enable them to erect works for supplying the metropolis, with the exception of the City.

Meanwhile, the City Corporation have bestirred themselves. The Gas and Water Committee were directed in December last to consider the bearings and consequences of a letter from the Gaslight and

THE ERICSSON PNEUMATIC TORPEDO.

A good deal has been heard in this country of the Ericsson torpedo, but it is only within the last few days that drawings of the weapon have reached this country. We are indebted to the *Scientific American* for the following information:—The body of the torpedo consists of a box of thin steel plates, 8ft. 6in. long, 30in. deep, and 20in. wide. The explosive is placed at the bow. During experiments a block of wood 27in. long represented the exploding vessel. A tapering block 16in. long and secured to the rear of the box forms the stern, immediately aft of which are the propellers. These are of the two-bladed type, 3ft. 2in. in diameter, with a pitch of 5ft. Both revolve around a common centre, yet in opposite directions, a necessary condition, since the powerful rotary movement of a single screw would cause the small hull to keel and probably revolve, unless retained in a vertical position by the ingenious expedient of causing the rotary tendency of one propeller to counteract that of the other. The displacement is greater than might be supposed, considering the small dimensions of the body, 2000 lb. being barely sufficient to balance the weight of the whole apparatus. The motive power is a small double cylinder oscillating engine, driven by compressed air, which is transmitted through a tubular cable, connected just abaft the stern, as shown in our engraving. The air pressure also governs an equipoise rudder, secured under the bottom and near the bow. The steering is effected by applying the force of the air against the tiller on one side, counteracted by the tension of a spring on the opposite side. The action of the apparatus is such as to be wholly independent of the differential force of the compressed air and the spring tension, and it is set in motion by admitting more or less air into the cable, thereby opening, more or less, a small connecting valve.

The submersion is regulated by two horizontal rudders turning on a transverse axle, with projects from each side over the bow. These wings or rudders are so contrived and governed that they keep the torpedo at a depth of from 7ft. to 12ft. below the surface, and are provided with automatic devices, so that the latter limit cannot be exceeded. In order to note the course of craft, a light steel mast is secured to the deck. This is 12ft. in length and terminates above to a wooden ball, the forward side of which is painted sea green, so as not to be perceptible to the enemy, and the rear white, so as to be easily distinguished above the water by those despatching the torpedo. Openings are made in the engine compartment, through which the water enters, completely filling the interior space. The machinery is made of bronze with box-wood bearings, so that the water serves as a lubricant to every portion, thus doing away with stuffing boxes at the rudders, and, besides, avoiding any danger of the mechanism failing to operate through rust or neglect to oil.

To the engine power of the torpedo no precise limit can be set. The whole force of the heavy engines of the torpedo boat, from which the weapon is despatched, may be used to compress air up to almost any desired point. Captain Ericsson informs us that, small as the craft is, it towed a scow, 40ft. long by 14ft. beam and drawing 2ft. of water, without trouble. Driven at a high velocity by its large screws, it seems probable that the machine would make light work of piercing ordinary torpedo netting, or at any rate the explosion of its heavy charge of 400 lb. of nitro glycerine, at such a short distance from a vessel as the length of her lower booms, would be sufficient to accomplish its purpose. Of course the torpedo hull is destroyed by the explosion, but this would be a trivial loss in exchange for the total wreck of an enemy's man-of-war. The cable, however, remains uninjured, for it necessarily becomes detached and may be readily hauled in.

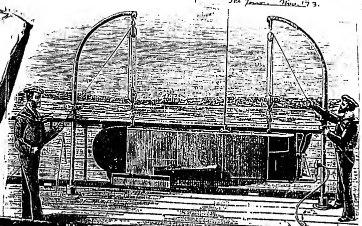
Our illustration represents the mode of launching the torpedo from the deck of the vessel. To this end the apparatus is hoisted upon swinging davits, the arms of which are previously turned over the deck. When lifted clear of the rail, the torpedo is carried out-board by revolving the davits, by bars inserted in the sockets in the broad portion of the davits, as shown. Nothing remains but to lower the machine into the water by the falls. The whole operation, we are informed, is accomplished in one minute.

A series of trials with the Ericsson pneumatic torpedo has lately been conducted on board the Intrepid, Commander A. P. Cooke, U.S.N., commanding, which has demonstrated the invention to possess a remarkable degree of efficiency. If further experiments, soon to be instituted from another torpedo boat, the Nina, prove, with slightly modified steering gear, as successful as the initial tests above referred to, we may fairly conclude that that long-sought weapon, a reliable fish torpedo, has at length been devised. As to the probable result upon naval warfare, it is only possible to surmise. Against the attack of the torpedo, there is practically no defence, for its approach cannot be seen. Armour plating, even did it extend to the keel, would prove no shield, and the Inflexible's one hundred and twenty water-tight compartments, which the English constructors hope will render her proof against such attacks, would fare badly under the terrible effects of 1200 lb. of gun cotton, with which Captain Ericsson says he could break any ironclad completely in two. We do not doubt but the same ingenuity which can devise a weapon of offence is equally competent to provide a means of defence, at least such has been the experience of the past, as evidenced by the almost uniform progress in guns on one hand and armour on the other; but what defence, save that of giving an enemy the widest berth possible, and fighting at enormously long range, is likely to prove efficacious, we are at a loss to conjecture.

A Treatise of Medical Electricity, Theoretical and Practical; and its Use in the Treatment of Paralysis, Neuralgia, and other Diseases. By JULIUS ALTHAUS, M.D., M.R.C.P., London. Third Edition, enlarged and revised, with 147 Illustrations. London: Longmans, Green, and Co. 1873.

WE are glad to see a third edition of Dr. Althaus's admirable treatise. Not many years ago it was customary for the medical profession to pooh-pooh the idea of electricity curing disease, but that time has, happily, passed away; and it is a rarity to find a physician who does not believe in the value of electricity as a therapeutic agent. Dr. Althaus has greatly enhanced the value of this work by incorporating the most recent discoveries, and so rapid are the strides of this branch of science, that with each edition his task becomes more difficult. The chapters in the present edition are as follows:—Chapter I. Forms of Electricity; II. Electro-Physiology; III. Medical Electric Apparatus, and methods of using it; IV. Electricity as a means of Diagnosis; V. Electro-Therapeutics. Each of these chapters are subdivided, and embrace every branch of the subject. The illustrations are numerous, and well executed. We shall return to this work as soon as our space will permit.

Tel Jour. Nov. '73.



25

every system of any promise being tried — McKean's, Burleigh's, Dubois and François', and others, all being used with various results. About thirty holes, a metre deep, are bored at one operation, and then charged with dynamite, and fired in the order shown in our illustration, Fig. 4, the drill-carriage being withdrawn eighty or ninety yards, and defended by a shield from flying fragments of stone. Figs. 9, 10, 11, 12, page 250, and Figs. 14, 15, 16, 17, &c., page 257, give illustrations of the progress of the works at the north and south ends respectively. These show the driving of the heading, the enlargement of the same, the turning of the masonry arch, the subsequent excavation, and the drain, and the final completion of the tunnel.

In future impressions we propose to illustrate the more important machines employed on the St. Gothard works, and we cannot better conclude this article than by the following tabular statement, which shows the progress of the works up to January, 1874. We may add that since that date they have progressed steadily, at, so far as we can learn, about the same average rate:—

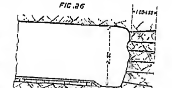
From a recent report made to the Swiss Federal Council it appears that, at the close of June, the contractors had completed nearly one-seventh of the whole distance. The progress made during July was about evenly balanced, but the advance on the Göschenen side was rather more rapid than that effected on the Airolo side.

... various systems of construction are adopted according to the nature of the ground. These are very fully illustrated and described at pages 256 and 257.

FIG. 26



ARRANGEMENT OF SHOTHOLES—VERTICAL SECTION.

The works were let by contract to M. Favre, of Geneva, in the summer of 1872. Seven tenders were received. Of these, two were withdrawn; a third did not supply satisfactory information as to the system of construction the contractor proposed to adopt; and of the remaining four, two were struck off the list. Only two competitors remained—M. Favre and the Italian Company of Public Works; but the latter required nine years to make the tunnel, and M. Favre only eight, and whereas the Italian Company would only forfeit the caution money—£320,000—if the work was not complete in eleven years, M. Favre consented to pay it over at the end of nine years. Again, the Italian Company wanted about half a million sterling more than M. Favre. The work began in June, 1872, at Göschenen, and at Airolo on the 1st of July in the same year.

FIG. 27

A NEW PHASE OF ELECTRICAL DEPOSITION.

Jan 77

[12101.]—THE following experiment, which exhibits electrical deposition under a new form, I have thought might possess some interest for a few of your numerous readers. I therefore send it for insertion in your valuable journal.

Having put a few drops of H_2SO_4 in a small quantity of paraffin oil to enable it to conduct electricity, I placed the terminals of a galvanic battery in the oil. No change appeared to take place during the first four or five days. Shortly after that period I noticed that the terminal from the copper-plate had diminished in thickness, and that its extremity was worn down to a point almost as sharp as a needle. The remaining terminal had, on the other hand, increased in thickness, and near its extremity was accumulated a deposit consisting of copper (the same substance as the terminals). The paraffin appeared to have undergone no change.

THE DETERMINATION OF LONGITUDE BY TELEGRAPH IN CONNECTION WITH THE TRANSIT OF VENUS.

THE numerous astronomical stations erected in places widely distributed over the globe for the observation of the transit of Venus offer an opportunity for determining longitudes such as has never before occurred. Moreover, the establishment of the electric telegraph enables this in many cases to be done with an accuracy which can be obtained in no other way. The process is specially interesting to astronomers and electricians; but the principles are so simple that they admit of being understood without difficulty by any person of intelligence. Any process of determining longitude depends on the very elementary fact that the world revolves in twenty-four hours. If then the time at one place is exactly twelve hours different from another, the two places are 180 deg. of longitude apart, or at opposite sides of the globe. So to learn the longitude of any spot on the earth taken from Greenwich it is necessary only to know two things—the local time and Greenwich time. The local star time is determined with a transit instrument; Greenwich time has to be arrived at by some less easy process. The moon's place will give it, for, if the moon falls back so as to pass over any station, say Greenwich, one hour later every successive day, and if it is known in what place among the stars she ought to pass the meridian of Greenwich, then it follows if she is seen to transit *half* an hour late anywhere, that place is 180 deg. west of Greenwich, or half-way round the world, for she has fallen back half the amount she would in the entire revolution. Jupiter's satellites may be employed in a rough way for the same purpose, but as we have said, by far the most accurate determination is obtained by simply telegraphing the time from Greenwich or from any other place with which comparison is made.

The difficulty of obtaining an accurate determination of longitude has been urged as one of the objections to the adoption of Delisle's method of observing the transit of Venus, which has been taken in hand by English, French, Russian, and German astronomers. It is, therefore, of great importance to the success of the expeditions that the telegraph has been established and can be used for many stations; but the value of obtaining the longitudes accurately of so many important points of the globe is permanent, and in no way confined to the questions connected with the transit of Venus. Many are not aware of the extreme looseness and inaccuracy of the longitudes laid down on globes and maps; but this fact known, the importance of seizing the present opportunity will be felt. The map on page 246 shows the lines of stations along which the telegraph will be, it is hoped, used with success, or on which it has already been used. It will be seen that they are on a gigantic scale, and with the longitude determinations that have already been made, will go far to establish correctly most of the chief geographical features on the globe. The longitude of several principal places in America—the lines A B C and D B C on map—have, during the last six or seven years, been determined by signals through the Transatlantic cable both from England and France—that is, from Valencia and Brest. As this operation has been

...of compressed gun-cotton can be effected by the ordinary combustion process.

New Electric Repulsion, and on its Application to the Theory of Comets.—E. Reitlinger and A. v. Urbanitzky.—If we approach the finger or any conductor to the luminous column produced in a Geissler tube we observe an attraction, which has been explained by the known laws of the electric influence. But on the 9th of March of this year we met with tubes in which the experiment, thus conducted, manifested, not an attraction, but a very distinct repulsion. These exceptional tubes have contained, according to M. Geissler, the one bromine and the other protochloride of tin. In addition to the repulsion there was observed in the tubes a green light, of a singular aspect, on the side towards which the luminous column was directed. Our researches showed us that this green light was due to a kind of electric phosphorescence, which we have described in the *Memoirs of the Academy of Vienna*. A spectroscopic examination did not reveal any distinction between the bromine tube and that which had contained protochloride of tin. In both cases the most distinct portions of the spectrum displayed those three well-known bands commonly attributed to the spectrum of carbon. They are the same bands which M. Vogel and others have designated as the spectrum of comets. This remarkable fact has drawn our attention to the relations between this repulsion and the repulsion exerted upon the tail of comets by the sun. The identity of the spectra may be explained by supposing that the gas introduced into the Geissler tubes no longer gives any light; that it is either absorbed by the electrodes or precipitated upon the glass; and that a trace of highly rarefied gas furnishes the luminous matter, the repulsive power of which has been observed. Chem News 1875

Condoling by Electricity.—On the recent occasion of the death of Mr. C. L. Goodwin, superintendent of the Northern New York division of the Atlantic and Pacific Telegraph Company, the various operators of the division united in a meeting of condolence in the following remarkable manner:—All the stations included in that division were connected into one circuit, extending from New York to Albany, thence *via* Troy to Saratoga and return to Albany, westward to Syracuse, and *via* Oswego, Clyde, and Rochester to Buffalo and Niagara Falls, back from Buffalo *via* Auburn, Seneca Falls, &c., to Auburn again, being over twelve hundred miles of wire. Each person remained in his own office, and all the instruments were so connected that the remarks made by one operator upon his instrument were sent through all the other instruments. Promptly at 2 p.m. (Buffalo time) New York called the meeting to order. Buffalo moved that Mr. Haeff, chief operator at New York, be made permanent chairman. The motion was seconded by Troy, and carried. The chairman then suggested that Mr. McCoy, manager of the Buffalo office, be nominated as secretary, which the meeting unanimously resolved in the affirmative. Various speeches were made, and the resolutions were then read and adopted, and an adjournment then followed. The meeting was entirely harmonious throughout, and the state of the weather and condition of the wires peculiarly favourable to its success.—*Scientific American.* 1873

POCKET PHOTOMETERS. 77

A new pocket photometer has lately been described to the French Society of Photography by M. Schutte. The instrument has exteriorly the form of a small telescope. Putting your eye to the narrow end, and looking through at a luminous source, you see a small, luminous circle, on which it detached some figure in black. On turning the wider part of the instrument, the more you advance in the series of numbers the weaker is the light perceived; and, at length, it quite disappears. This effect is obtained by means of leaves of waxed paper, the number of which increases with the figures. Thus, it will be understood that a weak, luminous source does not allow one to see the same number as a strong one, and the variation between the figures is greater the more difference there is in intensity. Thus one may be enabled to determine the proper time of exposure.

ELECTRIC VOTE-REGISTERS.

1875— Elec: News 1875

The following system of vote-registering, suggested by Mr. E. A. Jacquin, although totally differing from Messrs. Clérac and Guichenot's method,* possesses considerable merit. It does not, however, record its workings before the eyes of voters as Messrs. Clérac and Guichenot's system does, and partly for this reason it failed to be approved of for the National Assembly.

Two buttons are placed before each Deputy, who registers his vote by simply pressing them down; the nature of his vote being determined by the order in which they are depressed. Each button is an electrical communication with a small apparatus which encloses a supply of balls, and from which one drops whenever its corresponding button is pressed. The white-ball and the blue-ball apparatus are all ranged by themselves, and the balls fall from them into funnels, and thence through ramified pipes into two urns, by the force of gravity. They are all made exactly equal in weight; hence the number of Deputies who have voted is immediately obtained by weighing the urns.

In order to avoid as much as possible calculating the number of balls from the weight of the urn, the weight of each ball can be made 10 grms.—a very convenient size. Then on reading the weight of an urn the number of balls in it is directly proclaimed. Thus an urn weighing 1500 grms. would contain 150 balls. In speaking of the contents: the weight of the urn itself is previously balanced.

In addition to this, an automatic pointing is effected by each apparatus on small strips of paper introduced into it before the sitting, and the object of this pointing is to indicate the nature of the voting. At the close of the sitting, the pointed or dotted papers are withdrawn, collated side by side in numerical order, and form a complete detailed table of the votings for that sitting.

The battery for each Deputy, consisting of two Leclanché elements, is inclosed in a box bearing the Deputy's number, and the wire starting from the positive pole is in connection with an electro-magnet and thence to a kind of small metallic anvil; the negative pole through another wire is in metallic connection with a small lever placed above the anvil, from which it is held at a very small distance by a spring. The Deputy pressing upon a button, causes this lever to touch the anvil, and so to close the circuit through the electro-magnet.

The remainder of the contrivance, which each button works, is thus described:—

The electro-magnet attracting a lever releases a hinged pan containing the voting ball, and thus allows it to fall into a tunnel, whence it is conveyed to the urns. At the same time that the shovel drops, a pin affixed to its bottom causes the dotting upon the paper strip to which we have already drawn attention to be effected.

The recording sheet for each voting is divided into series of three small transversal and two vertical columns. The former may be called for convenience *a*, *b*, and *c*; the latter *d* and *e*.

In explanation, let us assume that voting is about to commence, and that the transversal column *a* is ready to be dotted. Deputy A, let us assume, is voting affirmatively. He presses his left-hand knob, and his sheet is struck in the affirmative vertical column *d*, in *a*. Then every paper is raised automatically, so that *b* transversal column occupies the late position of *a*. Our Deputy then presses down his right-hand knob, which produces a dot in the negative vertical column *e*, in *b*. Should he desire to vote against a measure, the order of pressing down the knobs which we have given must be reversed. In other words—

FIRING GUNS BY ELECTRICITY.

The system of firing guns by electricity while proving them, which is now in vogue in England, and which was employed in the case of the 81-ton gun, was adopted in 1856, up to which time the guns had been fired by fixing a piece of portfire over the vent by means of clay, igniting it, and then running under cover. The application of electricity was brought about by a curious accident. A number of guns were being proved in this way in the Royal Arsenal at Woolwich, and were placed for this purpose in a row on skids in front of the butts. The ignited portfires did not all burn at the same rate, and the result was that one gun went off before the others. This gun unfortunately burst, and one of the fragments, striking a neighboring gun, swung it round with its muzzle towards the arsenal, but without displacing the piece of ignited portfire over the vent. In due time the portfire fired the charge, and the gun projected its shot over the arsenal and town of Woolwich into the dockyard, where it fell, happily without doing any injury. This was in 1852, and another similar accident was narrowly escaped in 1855, when a mortar which was undergoing proof was swung round in the same way, but, fortunately, not until after it had discharged itself. Mr. M'Kinlay, the proof-master, was led by these circumstances to contrive a mode of firing guns by electricity. This he successfully accomplished in 1856, when the "galvanic tube" was introduced. In this tube a steel or platinum wire is embedded in a charge of powder, and this wire forms a link in the circuit of a galvanic battery. The retardation of the current, due to the inferior conducting power of the steel or platinum wire, causes it to be raised to a red heat, and by this means the powder is exploded. This system was in use until 1862, when the Abel "electric tube" was invented. In this the steel wire is replaced by a priming charge, consisting of subphosphide and subsulphide of copper, with a little chlorate of potash, and in this composition the terminals of the two insulated copper wires that conduct the electric current are embedded. The points of the wires are about one sixteenth of an inch apart, and when the current ... is sufficiently retarded by the separation of the wires and sufficiently accelerated by the sensitive composition to pass from one wire to the other in the form of a spark, by which means the tube is exploded. A magneto-electrical machine, specially designed for this purpose, is used for exploding the tube in preference to the galvanic battery, though any other electric agency could of course be used in doing it.

APRIL—MAY.

On Electric Fuses. By M. Ris.—The fuses employed for the electric inflammation of detonating mixtures may be disposed either for tension currents or for quantity currents. With the first the firing is produced by a spark generally resulting from induction apparatus; with the second, by the calorific action of energetic couples, of which the current is transmitted by a conductor of large section to a very fine platinum wire, which it heats to about 472° Fah. If it be attempted to fire an induction fuse by a battery current, a large number of elements is found necessary; and on the other hand, platinum wire-fuses can not be ignited by a tension current. The author suggests rendering induction fuses conductors, by incorporating with the detonating mixture (usually of chlorate of potash base) a small quantity of pulverized platinum sponge. Fuses are thus obtained, which are inflammable either by induction or battery currents.

[2826.]—Drum and Handle Commutator.—I remember once seeing in Ganot's "Physics" a sketch and description of a drum commutator. It was, if I remember right, similar to the following:—The circles in each figure are made of ebonite or wood, the seven black parts on it are metal, which are connected by wires in the order given in the diagram (of course the wires are insulated from each other). A A are metal springs, connected with the battery as shown. S S are similar springs connected, the one with the coil C C, and the line wire L, and the other with the earth-plate E. Fig. 1 shows the position of the commutator when the needle is vertical, Fig. 2 when the needle points to the right, and Fig. 3 to the left. In Figs. 2 and 3 the direction of the current is shown by the arrows.—Electron.

American Torpedo Vessel.—A new torpedo vessel, called the Alarm, has been completed at the Navy-yard, Brooklyn. This is the second of the kind built during the past twelve months, both being designed by Admiral Porter. The Alarm is entirely constructed of iron on the bracket plan, with double hull and bottom. She has seven water-tight compartments in the sides, and, whenever necessary, can be brought down in the water for the purpose of being trimmed. The Alarm is 170ft. long in the keel, 140ft. on deck, and 28ft. beam. She has 312 tons displacement, carrying one 20 in. gun on the bow, and when fully equipped will have four Gatling guns on board. There are three torpedo bars, capable of firing 50 lb. of dynamite, equal to 400 lb. of powder, and 100 loaded torpedoes, and about the same amount of cartridge and shot. She has stowage room in her bunkers for five days' consumption of coal, though, when necessary, she can carry on her deck coal sufficient for three days more. The engines and torpedoes are worked from the wheel house, and need but one person to work them. Accommodation is given to six officers and 60 men, and when out on duty she will carry two months' provisions. She is supposed to be very fast, and will be able to make 15 knots an hour easily.—*Times.*

June 1875

We noticed some time ago, says the *Pall Mall Gazette*, the force and originality of the views which Admiral Porter took occasion to impress upon his countrymen in the annual report on the United States' navy. Those of his suggestions which referred to the construction of a single small but efficient ironclad squadron, backed by a few swift corvette cruisers, to supersede the present antiquated and almost useless vessels on the list, remain still in abeyance. But the late votes of Congress have been applied partly to another, the improvement of the offensive torpedo service. Admiral Porter avowed his belief that torpedoes used merely passively would greatly disappoint their designers; and he even satirised the late experiments made by projecting them from the bows of slow, worn-out steamers. But he expects great things from a bold use of these weapons offensively by properly constructed vessels, and the new torpedo steamer, the Alarm, lately launched at Brooklyn, is the first attempt to give practical effect to his views. As in the case of the Dantzic torpedo boats of Germany, speed is a special object, and the lines are consequently fine and the engines powerful. But the Alarm is over 300 tons measurement, thus many times larger than the similar models of the Baltic builder, and is to carry one very heavy gun as a reserve, in case her torpedo boom fails, with Gatling guns for her own protection from boat attacks. As she is built with a wheelhouse, this, as well as her size, will prevent her having the comparative invisibility on which the German inventors much rely for the efficiency of their squadron. But, on the other hand, the Alarm is constructed to face a sea in which their low and fragile vessels would be quite useless.

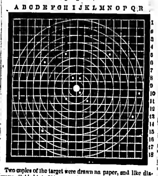
(33) TRANSMITTING SHOTS ON THE TARGET BY TELEGRAPH. —After the explanation we gave on page 1 of our January number for 1871, and which we illustrated by engravings, how portraits, drawings, and hand-writing can be transmitted by telegraph, the transmission of so simple a thing as the marks of shots on a target offers no difficulty, and can not be much of a secret. This indeed is so simple, that it does not even require the peculiarly constructed apparatus, but may be transmitted by letters and figures in various ways, one of which is illustrated in the following diagram:



Two copies of the target were drawn on paper, and like diagrams, divided into 324 squares by 18 vertical and 18 horizontal lines; the vertical columns were marked by 18 letters of the alphabet, the horizontal by 18 figures, and thus any square may be indicated by a letter and a figure. One of these diagrams is carried to Dollymount and one left here; at Dollymount the position of the shots on the target is copied on the diagram as near as possible, and every shot is then found to correspond with one of the squares. Thus for instance, the 11 bullet marks are placed in various squares, and may thus be expressed I15, K11, I11, N5, J10, R10, E6, I8, J8, E15, and Q13; these are transmitted by cable, and the corresponding squares marked here, from which the target may be reconstructed, the division line between I and J, and between 9 and 10 corresponding to the bull's-eye. It will be seen that this representation is not absolutely correct, but near enough for all practical purposes."

Electric Fall Machines.

These are for demonstrating the laws of falling bodies. In one arrangement, a brass ball is hung by a thread some hight above the ground. Under it, at distance=1, are two metallic balls connected with the poles of an electric machine; they are so far apart that a spark cannot pass between them, but if the suspended ball drop between them a spark will pass. Further down, at distance=4, then=9, etc., are similar pairs of balls. The thread of the suspended ball being burnt, the latter falls between the successive pairs, giving passage at each pair to the current, and simultaneously the spark in another part of the circuit strikes a revolving soot-blackened drum, making a mark. The distances between successive marks are found to be equal. In a second arrangement, there are two cylindrical conductors, insulated and vertical, with a metallic ball suspended between them at the top, hardly filling the interval, and sufficient to enable a spark to pass between the cylinders, which are connected with the poles of an induction (secondary) coil. One of the cylinders has a coating of soot-blackened paper. The thread is burnt, and the ball falls; sparks are made to pass at regular intervals of time, by means of clockwork, interrupting the battery current. Each spark leaves its mark on the blackened surface; and thus are shown the spaces passed over in equal times.—*M. Wahlner.*

THE TORPEDO PRACTICE AT NEWPORT.

The torpedo practice during the recent fleet drill at Key West, it will be remembered, was not exactly of a nature calculated to impress the public mind with a sense of the tremendous destructive force of bags of powder poked out on the ends of sticks; and consequently, since that time, slurs upon our naval torpedo system have been more frequent than commendations for the efforts of the very zealous corps of officers, who, for several years past, have been quietly working and experimenting, at their station on the bleakest of the islands in Newport Harbor. With the publication of the excellent results of the recent trials at Newport, however, the cloud which has obscured the labors of the experimenters is dispersed; and we must admit that, in lieu of sticks and powder sacks, the torpedo officers, Professor Moses Farmer and Lieutenant John P. Merrell, have developed for us a means of warfare of terrible efficiency.

The recent trials took place on successive days, in the presence of a congressional committee, and a large concourse of spectators. The initial experiment was the explosion of a ground torpedo of fifty pounds of powder enclosed in an iron-cased shell. This was blown up by Professor Farmer's dynamo-electric machine. Two fifty pound torpedoes were then fired by the contact of a boat with the circuit closers; and the blowing up of apparatus improvised from ordinary water breakers followed, to show how easily these destructive weapons could be constructed from the simplest materials, and without special machinery.

The plane table was used in the explosion of a three hundred pound torpedo, the current being established at the instant the approaching vessel was seen through properly adjusted sights. A column of water, two hundred feet high, marked the tremendous violence of the escaping gases. An attempt was made to blow up an old hulk, by the aid of submarine torpedoes; but through some mal-adjustment of the latter, the vessel, though badly damaged, was not destroyed. An excellent feature of the operation was, the firing of a torpedo through a mile of cable, the main object being to show that this means of offense or defense could be safely carried on beyond the range of the enemy's fire. An explosion of 500 igniters simultaneously, proving that several mines could readily be blown up at once, concluded the experiments of the first day.

An old coal schooner formed the objective point of the second day's operations, the interest of which was greatly heightened by the participation therein of the new ironclad torpedo boat Intrepid. This vessel is a small steamer, built expressly for torpedo manœuvering. She steams at a rate of about nine knots per hour. The hulk being stationed

Sci. Amer [SEPTEMBER 5, 1874.

out in the stream, the Intrepid backed astern for about a mile in order to get good way on, and then rushed ahead at full speed. The Harvey torpedo, which she towed on her starboard side, was brought in contact with the hulk and, at the instant of touching, fired by an electric fuse, smashing in a huge hole in the vessel's side. Immediately the Intrepid dashed up for a second trial, and this time exploded a spar torpedo, rigged out from her port side, directly under the bottom of the fated craft. A fearful explosion, followed by the hurling aloft of great fragments of wood and masses of water, showed that the weapon had done its work. The ship was literally torn to pieces, leaving but a few large portions drifting about. A second torpedo blew these out of existence, and the total disappearance of hulk marked the close of, probably, the most successful extended series of torpedo experiments conducted under naval auspices in this country.

The Manufacturer and Builde[r]

STEAM AS A MAGNETIZER.—Steam has been used as source of electricity in the steam electric machine of Sturgeon, already described in these columns; now it is announced by Donato Tommasi as a source of magnetism. He states that if steam of 5 or 6 atmospheres pressure is passed through a copper tube of one-tenth of an inch in diameter, wound as a helix around an iron cylinder, the iron will be magnetized, and attract other iron, act on the compass-needle, and manifest other magnetic phenomena.

We hope that this simple discovery will soon be verified by those who have the conveniences for such an experiment; if correct, it opens a new field of investigation, which to our great surprise has not been entered into by the alleged discoverer. The first matter for investigation must be to compare the steam current with the electric current, and to find if steam corresponds with the positive or with the negative current, that is, if the boiler giving the steam corresponds with the zinc pole of the battery or with the other, (carbon, platinum, etc.,) which question is easily settled by observing which end of the iron bar acquires north or south polarity. The next point of investigation is the increase and decrease of this polarity with the increase and decrease of steam pressure. The announcement being of such a nature as to appear incredible to us, we are anxious regarding its verification.

[21580.] Amalgamating Zinc with Mercury. A. J. Slade must put his zinc rod in a dilute solution of sulphuric acid, having the mercury on a plate. Take the rod from the solution, and with a little tow rub on the mercury and it will amalgamate.—W. INGHAM, Rochdale.

'75

[21580.]—Amalgamating Zinc with Mercury. —Your [illegible] amalgamating the zinc of your battery is quite the correct one—but you make a blunder if you suppose that amalgamation will prevent the zinc being eaten away. It will only do so while the battery is not in action, *i.e.*, when the current is not passing. So soon as the current passes, so soon is the zinc acted upon and dissolved. Were it not so, electricity could be had for nothing, and steam be a thing of the past. —S. BOTTONE.

[21580.]—Amalgamating Zinc with Mercury. —Put the rod into a strong solution of sulphuric acid and water for a few moments; take out, and plunge into water; brush the rod clean, particular care being exercised in brushing the holes in the rod; now dip again into the solution of sulphuric acid and water and rewash; afterwards pour over rod some mercury; then well rub the mercury into the zinc, and be particular in amalgamating the worn holes in the rod; the whole outside should have a dull silvery appearance; the presence of a dark surface will soon show its effects when battery is in action.—W. J. LANCASTER.

[21580.]—Amalgamating Zinc.—Do not do it for a Daniell battery, as it is mischievous, as it causes the copper to adhere to the zinc; use a half-saturated solution of sulphate of zinc, or else a strong one of common salt instead of acid, and the battery will work more steadily, only with a little less current, and with much less waste of material. Your zinc is probably cast, which is difficult to amalgamate; and, in fact, to amalgamate an old zinc for the first time requires very carefully cleaning with acid.—SIGMA.

[22382.]—Felling Trees by Electricity.—I am afraid "Landowner" will have to give up the idea of felling trees by heated platinum wire. The felling can be accomplished, but the cost will far exceed manual labour. Beside the first bulk of apparatus, and the great care necessary for transporting the batteries from place to place. Especially difficult would this be in a plantation or forest thickly wooded, and, again, the time occupied would be considerable. The sap and other juices in the alburnum and duramen would considerably impede the burning effect of the wire. I should imagine that some 500 Bunsen's cells would be requisite for an ordinary oak. Just picture to yourself charging 500 cells, if ever you have charged 50. I should imagine you would rather fell 20 trees with the axe than charge 500 cells to do the work; and besides this the platinum wire must be strong, and probably five feet long—this alone would cost from £7 to £10. I would like to hear what friend "Sigma" has to say on this subject.—W. J. LANCASTER.

Eng Mech May 28 '75

GERMANY now possesses two torpedo vessels, the Ziethen, which was constructed in England, and launched last year, and the Uhlan, which was launched at Stettin the other day. She has cost close upon £30,000. The Uhlan carries immediately under her bows a torpedo which is intended to explode within the vessel at which it is directed, and the force of the charge of dynamite which will be exploded by the collision is calculated to be sufficient to blow the other vessel to pieces, though the torpedo itself is no bigger than a football. Measures have been taken to protect as far as possible the Uhlan herself from being destroyed by the explosion. The *Broad Arrow* calls attention to the enormous power of her engines as compared to the vessel itself. They are of 1000-horse power when at high pressure, and take up so much room that there is little space left for the coal-bunkers and the berths of the officers and seamen. The unusual proportion of steam power has been given in order that the vessel may be able to travel through the water very rapidly. When the torpedo vessel is about to enter into action for the purpose of breaking the line of battle formed by the ironclads of the enemy, divers will attach to her bowhead fulminating cartridges, and she will proceed at full speed, the crew having in the meantime lowered and embarked upon a raft which is to be kept on board for that purpose.

Longitude by Telegraph.

The *Philosophical Magazine* has an article on the determination of the longitude of Cairo, from Greenwich, by the exchange of telegraph signals, by Captain C. Orde Brown. The actual experiments were between Porthcurnow and Alexandria, the whole series of cables being joined direct. The total length of cable was 3,222 nautical miles; 40 Menotti cells were used, although signals were read with 12 cells. The mean loss of time before the signal or make of circuit was visible was 1·31 seconds, and that before break of current signal was 1·28 seconds, the mean being 1·31 seconds.

July '76

Electricity as an Aid to Egg Hatching.

The *Oesterreichische Landwirthschaftliche Wochenblätter* states that Dr. Virson, Superintendent of the Italian experimental silk farm at Padua, has discovered that the hatching of silkworm eggs, of suitable age, may be accelerated by a period of 10 or 12 days, and a yield of at least 40 per cent of silkworm caterpillars secured, by exposing the eggs to a current of negative electricity from a Holtz machine for a space of 8 or 10 minutes. It is suggested that the same method might perhaps prove useful in promoting the hatching of hens' eggs and in hastening the germination of various seeds.—*Quarterly Journal of Science.*

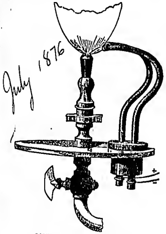
LIGHTING GAS BY ELECTRICITY.

The French Assembly Chamber at Versailles is illuminated by 856 gas burners, to ignite which, M. Gaiffe has devised the very simple arrangement represented in the annexed engraving. Two isolated bent iron rods terminate in platinum points, the ends of which are separated by about .0005 inch, and are placed exactly in that portion of the flame which is in contact with the air. All the ignitors of the same group of burners are connected together so as to form a circuit. Iron is

July 1876



LIGHTING GAS BY ELECTRICITY.

used for the connecting rods on account of its relatively-low conductibility of heat, and the platinum ends are placed as stated, so that the air current drawn into the flame will tend to cool them. The illumination is accomplished by merely establishing the necessary electric connection, and in fourteen seconds every gas-burner in the large hall is ignited. Substantially the same method of lighting is employed at the Capitol in Washington, and in the principal theatres and public buildings of New-York.

means alone the presence of the solid body can be often recognized; but in many instances the projectile becomes enveloped in the tissues or in a morsel of fabric carried in with it. This being the case, the solid mandrel is withdrawn and the canula only left in the wound. The rod of the revealer, Fig. 2, is then inserted, and the sharp points of the wires easily pe...

ELECTRICITY AS AN EXECUTIONER.

The revolting scenes accompanying the execution of several criminals in this vicinity are well calculated to bring to public notice the disadvantages of hanging as a mode of capital punishment.

The teachings of Science are heeded and sought for in the building of prisons, in the management and care of convicts, and in every modern correctional system; and yet in so simple and easy a process as the extinguishing of human life, they are utterly ignored.

The most certain and painless death known to Science is caused by the lightning stroke, or by, what amounts to the same thing, the electric shock. When a powerful discharge of electricity is received in the body, existence simply stops, and the reason is obvious. Helmholtz has proved that, for any vibration which results in sensation to reach the brain through the nerves, one tenth of a second of time is required. Furthermore, time is also needed for the molecules of the brain to arrange themselves through the effect of that vibration, through the motions and positions necessary to the completion of consciousness, and for this an additional period of one tenth of a second is expended. Consequently, if, for example, we prick our finger with a pin, it takes two tenths of a second for us to feel and recognize the hurt. It can easily be conceived, therefore, that if an injury is inflicted which instantly unfits the nerves to transmit the motion which results in sensation, or if the animating power is suddenly suspended by an injury to the brain before the latter completes consciousness, then death inevitably follows with no intervention of sensibility whatever.

Now a rifle bullet, which traverses the brain in the one thousandth of a second, manifestly must cause this instant stoppage of existence, and proof of this is found in the placid faces of the dead, and in the fact that there is nothing more common than to find men lying dead on battle fields, shot through the brain, but with every member stiffened in the exact position it was in when the bullet did its work. But a rifle ball is slow beside the electric shock. Persistence of vision impresses a lightning flash on the retina for one sixth of a second, but its actual duration is barely one one-hundred thousandth of a second.

The effect of the shock on the system is excellently described by Professor Tyndall, who, while lecturing before a large audience, inadvertently touched the wire leading from 15 charged Leyden jars, and received the whole discharge through his body. Luckily the shock was not powerful enough to be fatal; but as the lecturer regained his senses, he experienced the astounding sensation of all his members being separate and gradually fastening themselves together. He says, however, that "life was blotted out for a sensible interval," and he dwells with much stress upon the opinion that "there cannot be a doubt that, to a person struck by lightning, the passage from life to death occurs without consciousness being in the least degree implicated. It is an abrupt stoppage of sensation, unaccompanied by a pang." So much for the death which, by suitable alteration of the law, we would have substituted for slow strangulation. The next point is its practical accomplishment.

Instead of building a gallows and providing rope, the sheriff, advised by a competent electrician, would procure a powerful Ruhmkorff coil and a heavy battery. These instruments would rarely need replacing, and would last indefinitely for other executions. The battery and coil should be of sufficient strength to deliver an eighteen inch spark. In case of their being more than one person to be executed, all of the condemned would be conducted with all due ceremony to the place of execution, the left hand of one man handcuffed to the right hand of his neighbor, and the conducting wire fastened to bracelets on the disengaged wrists of both criminals, if only two are to be hanged, or in the wrists of the outer men, if more than that number are to suffer. The culprits being seated so as to be seen by the legal witnesses, the sheriff presses a button. The current is instantly established from the coil, passes through the bodies of the men, and all is over. With a competent electrician, who might be a member of the police force, and specially charged with the duty, there would be no possibility of mistakes. The same ignominy which attaches to the gallows would be transferred to this mode of destruction, while the peculiar death by lightning, which, among the ignorant of all nations and ages, has been the subject of profound superstition, would without doubt, through its very incomprehensibility and mystery, imbue the uneducated masses with a deeper horror.

J. F. H. says: "I have six volumes of the SCIENTIFIC AMERICAN, in which I can find nearly everything that is known as to engines and machinery."

21

CAN WE PROTECT OUR BANK VAULTS?

Aug 1876

Seven armed men recently entered the house of the cashier of the Northampton National Bank, at Northampton, Mass., and compelled that officer at the muzzle of the pistol to reveal the combination of his safe vault. Then they bound and gagged him and his entire family of seven persons, quietly waited until the bank's night watchman had departed, opened the vault and safe, and stole $750,000 in cash and securities. The annals of crime can show few more audacious robberies than this, nor do we know of one which has excited a wider spread feeling of insecurity or a more general distrust of all modern burglar-proof devices. Certain it is that no lock, however intricate, is safe so long as the means of opening it is in the hands of any one person; for no man, however brave, can withstand the persuasions of a night attack on his family and of a cold pistol barrel pressed against his temples in order to make him hand over his keys or divulge the information demanded. It may well be asked if seven men can plan and successfully carry out such a scheme, whether twice seven men could not perpetrate even a more gigantic robbery; and when we consider the matter in the light of the elaborate precautions taken by the thieves and their intimate knowledge, which they spend weeks in acquiring, of a marked point of attack (all detailed recently by a convict captured in a similar undertaking), it is but natural at first to doubt the safety of any bank or strong box. But on the other hand, it is reasonably certain that, if the Northampton bank people had been as vigilant as the thieves, the robbery could not have occurred; and it seems to us that, if the means which Science offers for protecting our valuables were fully used, such robberies would be impossible, or at the least be very difficult, of perpetration. Suppose, for instance, a chronometer lock had been in action on the Northampton safe. Then what would have availed the binding and gagging of the family of the unfortunate cashier, and an assault on his person, since he would have been as powerless as the thieves to enter the stronghold? At a certain time next day, when all the employees of the bank would be at their desks, the safe could be opened; until then, if properly made, nobody could stir its doors. Rendering it the duty of two bank officers, one as a check on the other, to assure themselves that that lock was in working order at the last thing before closing the bank for the night, would prevent any tampering with the mechanism; and should the lock be inoperative, the very circumstance would instantly suggest extra vigilance during the night and until the difficulty could be remedied.

Another safeguard is found in never trusting the means of opening the safe to a single individual, a plan frequently adopted in banking institutions in cities. There might be, for instance, three locks to a door; and the key or the combination which throws back each could be in the possession of a different officer, so that no one of the trio could enter alone. This would necessitate the robbers intimidating three persons instead of one. Or the knowledge of a combination might be kept a secret, by the president, for example, and the cashier possess only a key to be used in connection with the combination.

There is much safety to be found in properly constructed electric devices. Why, for example, has not somebody invented a thief catcher—a couple of metal knobs which must necessarily be turned in attempting to open a door? At night, lead a powerful interrupted battery current to these knobs. When the burglar grabs them they will grab him, for he cannot let go, as every one knows who has tried to release the handles of the simple magneto-electric machines from which itinerant scientists at country fairs offer to administer shocks for a penny or two each. The burglar, besides, will get so thorough a shaking that he would convert himself into an alarm, and yell loud enough to awaken any somnolent neighborhood. Electric wires might be laid from every door in the bank to convey an alarm, say to a police station or any other desired point; and if those wires were so placed that cutting them in advance could quickly be told through the breakage of the circuit, tampering with them could be found out in time and proper precautions taken.

It has been suggested that the next advance of the thieves will be a day attack on a bank, through the use of an exploding shell tossed in among the clerks, and a rush for the funds in the confusion. For this, the only remedy appears to be constant watchfulness, or the encasing of the people handling money in a separate armored room, and not dividing them by a mere wood and glass partition from the crowds which often congregate outside the tellers' windows. We have some banks in our mind whose counting rooms are very poorly suited to withstand an attack of the above kind.

We think that there is abundant ingenuity in this country to provide means of frustrating the smartest and most audacious of burglars; and that if inventors will set about it, devices much more efficacious even than those which have occurred to us can be produced. At any rate it is hardly time to suggest the abolition of banks, as does a daily contemporary of this city, and thus admit that we are outwitted by rascals, until we have seen what the inventors can do, and certainly not before we have fairly tried the safeguards with which we are already provided.

32

Electricity as an Executioner.

To the Editor of the Scientific American:

In your paper of January 8 is an article on the above subject. It is very suggestive. Should the electric field be used to shuffle off the mortal coil of criminals, the judge in pronouncing sentence would have to say: "The sentence of the court is that you be taken to the county jail, and thence to the place of execution, where you will be struck with lightning until you are dead, dead, dead!"

We might go still further with improved methods of dealing with culprits. Experiments could be made to determine whether human beings could be frozen in such a manner that life would return when the body was thawed out, as is the case with fish and other animals. If successful, instead of long imprisonment at the expense of the State for food and clothing, and the risk of escape, criminals could be securely incased in blocks of ice, and stored away in refrigerators during their allotted term. Had Tweed been thus immured, there would now be less anxiety about him. Then, again, any one dissatisfied with the hard times could step into the machine, and request a friend to block him up in ice until specie payment was resumed.

The length of this kind of improvement would add years, but not age, to the prisoner. With proper care, we should be immortal. A hundred years would be as one day. Troublesome mothers-in-law could be disposed of for a time, care being taken not to break them in two in the act of storing.

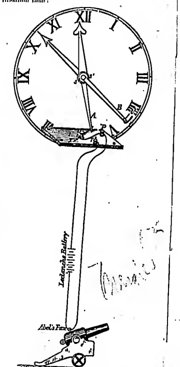
THE TORPEDO SHIP "ZIETEN."

The torpedo question was practically advanced another step yesterday week by the launch of the Zieten from the yard of the Thames Iron Works and Shipbuilding Company, at Blackwall. This vessel has been built for the torpedo service of the Imperial German Government, and she is intended to carry out a series of experiments at sea with the Whitehead or fish torpedo, the patent right of which the above-mentioned Government acquired last year. The Zieten is an unarmoured iron-built ship 226 ft. long, 28 ft. broad, and 18 ft. 6 in. deep. Her burden is 872 11 tons, B.M., and her load draught 11 ft. 8 in. She will be propelled by twin screws which will be driven by a pair of engines by Messrs. J. Penn and Sons of 2500 indicated horse power, from which a speed of over 16 knots is anticipated. The Zieten is fitted with two tubes placed in line with her keel, one forward and the other aft. They are 6 ft. below water line and from them the torpedo is to be expelled by means of compressed air. The outlet of the forward tube is about 16 ft. back in the fore body of the ship, and a triangular portion of the hull is made to hinge in the stem and lift into a water-tight well, so that there is no projection to interfere with the speed of the vessel. The Whitehead torpedo as acquired by the German Government is, we are informed, an advanced example of the weapon. It is cigar shaped, 16 ft. 6 in. long and 1 ft. 3 in. in diameter at centre. Within the torpedo is a chamber for containing the compressed air with which the propeller of the weapon is to be worked. The torpedo is to be expelled from the tube at a speed of 20 knots per hour, and after expulsion a speed of 12 knots is to be obtained by means of the self-contained propelling power of the torpedo. It is expected that this speed will be maintained for a distance of 600 yards under water, the true line of horizontal travel being preserved by regulating mechanism with which the weapon is provided. It has of course to be determined by experiment, and by very careful experiment too, whether this weapon will prove successful, and justify the time and money which have been expended on it in our own and other countries. If it realises all the expectations formed of it, and can be truly delivered from a ship more or less in motion riding on the sea, against another ship similarly circumstanced, perhaps moving with full steam on and discharging her guns at the torpedo vessel—if, under these circumstances, the Whitehead torpedo prove effectual, then it will be one of the most remarkable inventions of the age. The launch of the Zieten took place in the presence of a distinguished company, which included Count Münster, the German ambassador; Countess Bismark, who christened the vessel; Baron Brinken; Admiral Stewart; Mr. E. J. Reed, C.B., M.P.; Mr. Barnaby; Mr. Zacnack, the designer of the Zieten, and representatives of the Austrian, Turkish, Spanish, Portuguese, and other governments.

THE ELECTRICAL TIME GUN AT PERNAMBUCO.

The following description of the manner in which the time gun is fired at Pernambuco is given by Mr. Andrew Jamieson, assistant engineer and electrician on the Western and Brazilian Line:



Thermics

In the above sketch the large circle is to indicate the dial face of the large clock fixed in the tower of the Arsenal de Marinha, Pernambuco, which, you may remember, is some 400 yards from the S. and B. Telegraph Office. S is the hollow spindle of the hour hand, S_1 the spindle for the minute hand. To these spindles I firmly fixed, at about four feet from the face, or inside end of hour hand spindle, two large levers, A and B, two feet in length, and diametrically opposite to the clock handles (inside the tower). To the end of lever B was attached two platinum-pointed springs, the points of both levers A and B being well *insulated* from their attachment to the minute hand spindles by the intervention of suitably arranged pieces of ebonite. Immediately underneath the plane of motion of these levers (A and B) was fixed on a neat mahogany stand an ebonite slab (t) of some 10 in. by 6 in. by ¾ in., at the centre of which was screwed a terminal O, with a lever L radiating upon O in a horizontal plane, but unless acted upon was kept in an angular position, by a light spring, across the length of the ebonite slab. This spring and lever L were so adjusted that when the hour hand came to ten minutes to twelve, noon, the end of lever A fixed to same spindle (as the time drew nearer and nearer to twelve) made contact and gradually brought L to a position at right angles to the length of the ebonite slab, whereby the other end T_1 of L was now in a position to make contact with the more quickly passing lever B at its platinum point t_1, and at the same moment (the sixth stroke of the clock) spring t_2 causes in contact with a spring attached to terminal T_2, which is in electrical connexion with one pole of a 30-cell Leclanché battery, the other pole communicating by means of an underground cable, with one side of an Abel's patent fuse inserted in the touch-hole of the cannon, while the other side of fuse is returned to the central terminal (O) of lever L by another wire attached to P, and from thence by wire to O, so that when t_1 touches T_1, and t_2 T_2, the circuit is completed, the fuse exploded, and the gun fired. The levers A and B move on, L falls back to its angular position under action of the aforementioned spring, and is only affected by A and B twelve hours afterwards, but as the ends of the cable are freed by the explosion, and the gun only loaded once in the twenty-four hours—namely, at 11 A.M.—the electrical current flows but once in the twenty-four hours.

ELECTRICITY IN EAR DIAGNOSIS.

A diseased ear can not be considered fully examined and the means for its cure exhausted, until the galvanic current has been used in a scientific manner. It has been observed, both by ourselves and other careful observers, that a sensation of sound is perceived, even in the healthy ear, when one of the poles of a battery is placed in the auditory passage when filled with salt and water, and the other connected with different parts of the body.

Some recent writers are in doubt upon this subject, and state that this has not been proved to their satisfaction; and

No. 12. March 18, 1876.

some recent experimenters attribute the subjective auditory phenomena observed by Brenner and others to stimulation of branches of the facial, and through this nerve to the action of the muscles of the middle ear, particularly the stapedius.

Dr. Poorten, in a review of the theory concerning the origin of the subjective symptoms consequent upon the application of the galvanic current, gives the results of experiments upon himself and others, and disproves the theory, founded by Wreden, upon the supposed action of the current upon the stapedius and tensor-tympani muscles. The experiments consisted in the use of Siegle's pneumatic speculum (before referred to), by which the membrana tympani was drawn outward, and traction made upon the tensor-tympani and ossicles, or, on the contrary, relaxation. Under these circumstances, the galvanic current gave precisely the same reaction that it did before the use of Siegle's speculum. Dr. P. concludes that the action of the stapedius muscle by Wreden (namely, the production of intra-labyrinthine pressure by its contraction) is not only disproved, but is denied by later observers. That neither the facial nerve, the branch of that nerve passing to the stapedius muscle, nor the muscle itself, are directly acted upon by the galvanic current. Subjective symptoms were educed by the action of the galvanic current, when the contraction of the stapedius muscle was prevented.

We firmly believe that the auditory nerve can be excited by the galvanic current, if properly applied, and there is no resulting paralysis. We have performed numerous experiments upon our own ears, as well as other persons'. The mode of its impression, or the way that it is connected with that nerve, may be by the facial, for we know that there is in the internal auditory canal a few fascicles of fibres, which constitute what Wresberg has termed the "portio-intermedialis," forming a connecting link between the auditory and the facial. Confirmation of the above has been given by means of the rods of Koenig.

Blake finds that the passage of the current increases not only the limit of perception of musical tones, but also the intensity of perception—the degree of increase in intensity of perception being a measure of the degree in which the auditory nerve responds to the stimulus. We believe that the galvanic current is a most valuable auxiliary in the treatment of diseases of the ear, and must not be omitted, especially in cases of a nervous character, after all symptoms of disease of the external and middle ear have disappeared or been removed. Of the mode of application, which is of importance, and the kind of electricity which is most useful, we are unable to enlarge at this time.—*Medical and Surgical Reporter.*

ELECTRIC CHRONOGRAPH.

Captain Watkin, R.A., exhibited a series of instruments for assisting artillery operations in time of war, and an electric chronograph for measuring very minute intervals of time by the free fall of a weight. These also would require drawings and more space than we can spare on the present occasion to render them intelligible to our readers.

Sc. Am. Supp. June 9/76

GREAT INDUCTION COIL.

In the meeting-room of the Royal Society, Mr. Spottiswoode, Treas. R. S., showed his giant induction coil. Discharges through large vacuum tubes by this fine instrument illustrated in a remarkable manner the two induced currents produced by the "make" and the "break" of the primary current as well as the striæ and stratification of the discharge.

The soirée was very largely and influentially attended; there were but few absentees of men celebrated in science, and among other eminent guests we noticed the Marquis of Salisbury, the Poet Laureate, the Duke of Teck, Dr. Schliemann, and Sir George Nares. We are only expressing the feeling of every one who was present when we congratulate Dr. Hooker and his Council on the eminent success of the evening.—*Engineering.*

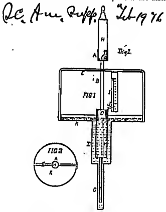
NEW PHOTOMETER.

By P. Munzinger, Philadelphia, Pa.

Figure 1 is a vertical diametrical section; Fig. 2 is a reduced plan view.

Consists of a candle-socket A on the end of an axial rod B, of a float C, contained in a water-chamber D. The vertical motion of the float is retained at the top by the socket-rod passing through a guide-frame E, and at the bottom by an axial guide-rod F of the float and a guide-tube G, which forms a reduced extension of the chamber D. A candle H is placed in the socket A, and water is poured in the chamber D until the float C rises to the zero-point of the stationary

Sc. Am. Supp. Feb 1976



NEW PHOTOMETER.

scale I (graduated in grains), as shown by the index J fixed to the float. On the candle being lighted, its burning and consuming increase the specific lightness of the float, which gradually and imperceptibly rises in the water, and keeps the burning-point of the candle, without variation, at the same altitude. The index J, rising with the float, shows on the scale the candle consumed in grains. To preclude any possibility of the chamber D not having sufficient water capacity to float the index J to the zero-point of the scale, a dish or an enlargement K of the chamber D can be used to hold the additional supply of water.

A TORPEDO COLLEGE IN CHINA.

The first quarterly examination of the students of the Imperial Torpedo College, Tientsin, China, was held (says a correspondent in that country) on the 21st July, under the direction of His Excellency Li Hung Chang. The College was removed from Foochow to head-quarters at Tientsin, in April last. There are at present thirty-six students, which number it is intended to bring up to forty. Several of the students have received a thorough English education at the Government Schools at Hong Kong, while others have passed a three years' course at the Naval Schools at Foochow Arsenal. His Excellency Li Hung Chang arrived at the College at 8 a.m., and the examination at once commenced. The subjects for examination were—Proficiency in the English Language, Translation of English into Chinese and *vice versâ*, Telegraphy and Electrical Testing, &c. In the afternoon a large number of torpedoes were placed in position by the students, and the use of the "firing arcs" shown by the Director, Mr. J. A. Betts, M.S.T.E.; rafts representing boats were destroyed as they passed over the various lines of torpedoes, the officials seeming much impressed with the precision with which each particular torpedo was fired. Some experiments were made with gun-cotton manufactured at the College.

DRIVING HORSES BY ELECTRICITY.—The French papers tell us of a wonderful invention, which will enable the feeblest among us to "witch the world with noble horsemanship." The horse of the future is not to be driven by ordinary reins, but by electricity combined with them. The coachman is to have under his seat an electro-magnetic apparatus, which he works by means of a little handle. One wire is carried through the rein to the bit, and another to the crupper, so that a current once set up goes the entire length of the animal along the spine. A sudden shock will, we are gravely assured, stop the most violent runaway or the most obstinate jibber. The creature, however strong and however vicious, is "at once transformed into a sort of inoffensive horse of wood, with the feet firmly nailed to the ground." Curiously enough, the very opposite result may be produced by a succession of small shocks. Under the influence of these the veriest screw can be suddenly endowed with a vigor and fire indescribable, and even the Rosinante of Don Quixote would gallop like a Derby winner. What is the effect upon the condition of the horse is not stated, but the Siècle finds itself able to congratulate M. F. Faucher upon "an invention equally original and salutary," and one which places in the hands even of an infant a power over the horse which is as sovereign as it is invisible.

NOTES ON TORPEDOES.—No. III.

CIRCUIT-CLOSERS.

THE efficiency of electrical torpedoes must necessarily depend on the self-acting arrangement employed for closing the electrical circuit when the buoy enclosing the mechanism is struck by a passing vessel. To contrive an efficient apparatus for effecting this has in consequence been the chief aim of those inventors who have given special attention to this branch of electrical science.

But although, as we have remarked, the circuit-closers have monopolised the greater share of attention, the various appliances appertaining to them and requisite for their perfection as a means for bringing about the explosion of submarine charges, have not been neglected, as the elaborate instruments in present use sufficiently testify.

The exhaustive series of experiments which were instituted by the Government and carried out in the Medway, with a view of ascertaining the merits or demerits of the relative circuit-closers invented by Professor Abel and Quartermaster-Sergeant Mathieson, afforded marked proof of the superiority of an arrangement employing no exterior mechanism over that which necessitates the use of external appliances for communicating the blow of the ship to the internal apparatus.

Fig. 1.

Fig. 2.

The form of circuit closer employed by Professor Abel during these experiments is shown in the illustration, Fig. 1. Outwardly it is not the best form, the three iron legs on which it stands giving it a clumsy appearance, but it possesses the advantage over those previously invented and experimented on by him, of enclosing a water-tight chamber for supplying the requisite buoyancy.

The general electrical arrangement is similar in character to Professor Abel's earlier circuit-closers, the electric chamber being formed by a fixed brass cylinder passing vertically through the centre of the vessel. Within this cylinder, which is left open at both ends, a movable brass tube extends vertically through the entire length, its lower extremity working upon a universal joint, while the upper end projects through the top of the vessel and is attached to a strong teakwood disc resting upon the outer case and projecting slightly beyond its rim. Encircling the upper extremity of the brass tube, is a thick india-rubber ring which serves to hold the whole combination rigid, and by its resistance varying with its thickness regulates the force which must be used to close the electrical circuit by reducing the distance between the contact points.

Referring to Fig 1, I is the wood jacket constructed of well seasoned timber, cut into segments, dowelled together and bound with wrought-iron hoops shrunk on and secured by means of coach screws; J is a portion of the apparatus which protrudes below the enclosing vessel, K K K are three iron legs or feet to which is attached a three-legged mooring chain; G is the wood disc for receiving the concussion of passing vessels, and H the hoisting ring.

The closing of the circuit is accomplished by attaching to the upper end of the movable brass tube an ebonite collar, which serves to insulate a copper band encircling it; this band is separated by a small space from a corresponding metallic ring attached to the fixed tube, but insulated from it by means of a collar of ebonite.

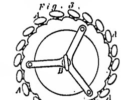
At the lower extremity of the cylindrical chamber two insulated wires are introduced, one of which is soldered to the copper ring surrounding the movable tube but insulated from it; and the other is connected in a like manner to the insulated brass ring attached to the fixed cylinder. This arrangement may be better understood by reference to Fig. 2, which represents a section of the electric chamber showing the contact rings; A is the fixed cylinder, B the movable brass tube, E D the ebonite collars, C, F the metallic rings, and X X the insulated wires.

It will from this be easily understood that a blow imparted to the edge of the external teak disc would be transmitted to the movable tube B, by which means the metallic rings F G would be brought into contact and the circuit at that point closed.

The principal demerit of Abel's circuit-closer is its inability to fuse platinum wire with uniform success. And in addition to this the necessity of an external appliance for communicating the blow of the ship to the interior apparatus marks it as much inferior to those circuit-closers which possess the advantage originated by Captain C. A McEvoy, of employing no external mechanism to set the apparatus in action, while its liability to get out of order is alone sufficient to justify its non-adoption.

On the whole we are inclined to think that the only feature of merit which the invention possesses, is the employing of a water-tight chamber for supplying the requisite buoyancy, entire dependence on wooden bodies for this purpose having proved objectionable in practice, from their liability to become water-logged after having been in use a few months. Fig. 3 represents a plan of the Austrian circuit-closer, which, although objectionable from the employing of external appliances for actuating the interior mechanism, is superior as regards its circuit-closing properties to the one designed by Professor Abel. The circuit-closing arrangement consists of a nave turning on a fixed centre, and fitted with a series of arms equal in number to the external buffers A A A, with the plungers of which their extremities make contact, the arms being so arranged, that the striking of any one of the buffers, and consequent forcing of the plunger into the interior, communicates itself to the nave by means of the arm corresponding to the buffer struck, thereby causing it to revolve through a fraction of a circle, and thus abridge the distance between two contact points placed near the centre of the apparatus, and so closing the electrical circuit.

Fig. 3.



The mechanism is rendered self-adjusting by means of suitable springs, which also serve to keep the whole combination rigid while at rest.

As far as we have been able to learn, the experiments made with this circuit-closer by the Austrian Government have been fairly successful. But however good the result obtained may appear, the necessity for employing external machinery for communicating the blow of the ship to the interior apparatus marks it as objectionable, and much inferior to that class of circuit-closers which, having no exterior appliances, are capable, like McEvoy's cheap and simple contrivances and Mathieson's more elaborate and costly apparatus, of being enclosed in a buoyant chamber of any shape and any material.

Captain C. A. McEvoy's circuit-closers have been fully described by previous writers on the subject, and are in consequence pretty generally understood, we shall therefore make our description of them as brief as possible. Each of these cheap little contrivances possess the merit of great simplicity. They have, as already stated, no external mechanism, and are furnished with air-tight chambers to impart adequate buoyancy. His circuit-closer, patented 1871, consists of a brass tube 1 in. in diameter, at the upper extremity of which the apparatus occupies a length of about 4 in.; in this space an ebonite cylinder is fitted, plugged at its lower end; through the plug is fixed a wire spring carrying a metal ball. At the upper end of the inner surface of the ebonite cylinder, a metal ring is let in, so as to partly surround the metallic ball, a thin metal bridge crosses the upper end of the ebonite cylinder, and is in constant contact with the ball, so long as the spring and ball remain in a central position, but on being disturbed by the concussion of a passing vessel, the ball is thrown from its central position, and makes contact with the surrounding metallic ring, resuming its original position immediately. The method of connecting up this instrument for service is very simple, and may be easily explained. An insulated wire leading from the electric battery on shore, is attached to the fixed end of the spring carrying the metal ball; electricity will thus flow through the spring and ball, along the metallic bridge to the outer metal tube, and so to the outer iron case of the vessel, which serves for earth. This arrangement furnishes a constant test for insulation.

To cause the ignition of a charge, a second insulated wire is used, one end of which is attached to the insulated metal ring surrounding the metallic ball, the other extremity being attached to the electric fuse. The current of electricity in this case would, on the concussion of a vessel throwing the ball from its central position against the insulated metallic ring, be diverted from the bridge to the metallic ring, through the fuses to earth, and so explode the tube.

McEvoy's second circuit-closer, in which the closing of the circuit is effected by the canting of a conical weight, occupies a slightly increased space. As in the case of his previous invention, the apparatus is enclosed in a cylinder placed in the upper end of a brass tube; the base of the conical weight rests on the bottom of the cylinder, through which a spindle passes, and is pressed up against the weight by means of a spring. Attached to the spindle, but insulated from it, is a strip of metal held down by the conical weight, out of contact with two metal tongues, to which are coupled two insulated wires, one of which is attached to the cable leading to the electric battery, and the other to the outer iron case (or earth).

When the vessel is struck with sufficient force to incline it beyond a certain angle, the conical weight is momentarily tilted over, relieving the spring, and allowing the spindle to rise until the strip of metal makes contact with the two metallic tongues, thus completing the circuit.

McEvoy's third circuit-closer, by reason of its extreme simplicity is especially adapted for use in all kinds of electro-mechanical torpedoes. It consists of a small ebonite cylinder fitted with a metallic cap, to which is attached one pole of the battery. The ebonite cylinder is partly filled with mercury, which is in electrical contact with a metal pin passing through the base of the ebonite cylinder, and in connexion with the other pole of the battery; the circuit is completed by a blow jolting the mercury into contact with the metal cap.

We understand that in addition to the mercury circuit-closer which we have described, Captain McEvoy employs another arrangement in which the closing of the circuit is also effected by the agency of mercury. A sectional elevation an

WEIMER'S CHARGING APPARATUS FOR BLAST FURNACES.

CONSTRUCTED BY MESSRS. WEIMER AND BIRKENBINE, ENGINEERS, LEBANON, U.S.A.

(For Description, see following Page.)

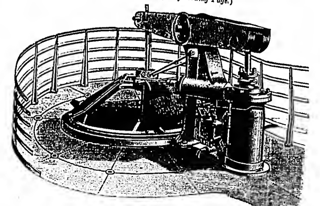


FIG. 1.

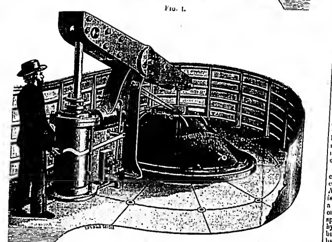

FIG. 2.

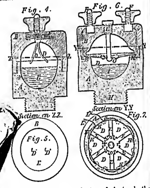
plan of this contrivance is shown in the illustration, Figs. 4, 5. It consists of a brass cup A, made with a screw projection for securing the apparatus to the upper end of a brass tube similar to those already described as being employed in his previous circuit-closers. B is an ebonite cap fitted with a brass terminal C, to which is connected one pole of the electric battery, the other being put to earth. To the lower extremity of this terminal two metal tongues D D are soldered, their tips being separated by a small space from the mercury E contained in the brass cup A.



It is obvious that when the torpedo is struck, the surface of the mercury becoming agitated would make contact with the metal tongues D D, thus completing the circuit, the current of electricity flowing from the battery along the insulated wire to the terminal C by the tongues D D, to the mercury E and cup A along the brass tube to the outside of the iron vessel to earth. The ends of the tongues D D should be platinised in order to insure as perfect a contact as possible, unplated copper being objectionable from its liability to corrode.

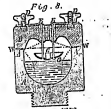
A design for another mercury circuit-breaker is given in our illustration, Figs. 6, 7. It consists of a metal cup A containing the mercury and fitted with an ebonite cap B, into the centre of which a metal pin C is secured, to carry the contact-breaking disc shown in section at G D. Ebonite arms, E E, project from an ebonite boss, these arms serving to insulate from each other the metal bridges D D D, turning on a swivel joint at J. K K K are platinum contact points, and L L' two insulated wires in connexion with the opposite poles of an electric battery. It will be easily understood that when one pole of a battery, the other pole of which is put to earth, is connected with the insulated wire L', the current will travel from K to K by means of the conducting wire M, employed to unite each two contact points separated by the ebonite arms E, and traversing the intermediate space by means of the metallic bridges D D D, would flow to the insulated wire L and so to earth. When the vessel enclosing the apparatus is struck by any hard substance, the mercury F is jolted against one or more of the metallic bridges, momentarily raising it out of contact with the contact points K K and so breaking the circuit.

As a portion of the mercury would in all probability escape into the upper cell during the motion of the instruments, two small ports are provided at G by which it may be returned again to the lower cell.

It is obvious that the apparatus just described could be inclined until its vertical axis assumed an horizontal position without breaking the circuit, for as the mercury by reason of its weight raised the metal bridge or bridges, it would flow in and establish a circuit connexion between the points K K. Of course this could not occur in any case of concussion with passing ships, the vibration of the apparatus and inclination at which the contact points are set obviating all possibility of it doing so, even were not the mechanical action set up in the instrument by concussion totally different to that produced by the rolling motion of the waves.

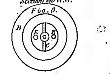
Figs. 8, 9, illustrate again another form of mercurial circuit-closer. The closing of the circuit in this instance is accomplished by the concussion of a vessel jerking the mercury into a small receiver, from which it returns again to its original position through a small hole pierced in the centre of the base.

Fig. 8.



Section on W.W.

Fig. 9.



The receiver is formed of two metallic sections secured together, but insulated one from the other by means of a strip of ebonite, and is provided with a narrow ledge running round the interior of the rim, in order to prevent the mercury that had been thrown into the receiver by the concussion of a ship being again ejected by the recoil. It is apparent that so long as any mercury is contained in the receiver, the small insulated space between the two metallic sections would be bridged over and the circuit closed.

The apparatus will be easily understood on reference to the sketch, A is an ebonite cup fitted with a cap B, also of ebonite, C the receiver, held in position by the conducting wires E E connected with the terminals D D, and G is the mercury, which may either be contained in a vessel of the form shown in our illustration, or as represented by the dotted lines.

Should the buoyant vessel enclosing the instrument not be struck with sufficient force to jerk the mercury into the receiver, the closing of the circuit would still be effected, though less perfectly, by the contact of the mercury with its exterior. But if the form of cell shown by the dotted lines be employed, it will be necessary to insulate the whole of the external surface of the receiver, in order to prevent the closing of the circuit being brought about by the rocking motion imparted to buoyant objects by the action of the waves.

Captain C. A. McEvoy's circuit-closers are each constructed to act as breakers or closers of the circuit as desired. This is accomplished by adding or removing a spring in the spring ball instrument, a washer to the conical weight, or a small cup to the mercurial machine.

ALLEY'S BEARING FEELERS.

Nearly eleven months ago (*vide* page 120 of our nineteenth volume) we illustrated and described an arrangement of "feeler" for bearings, designed by Mr. Stephen Alley, of 28, Hanfield-street, Glasgow. This "feeler" consisted of an arrangement whereby the melting of a plug of hard lubricant caused by the heating of a bearing allowed a spring to drive a hammer and make a number of strokes on a bell, thus calling attention to the fact that the bearing had become heated. This arrangement acted well, and was successfully applied on shipboard; but for mills and factories, where the attendants are often absent from the engine rooms, &c., an alarm continuing a longer period was desirable. This led Mr. Alley to design the modified arrangements we illustrate on page 96, in which the alarm is given by a tapper fixed to the revolving shaft striking against the clapper of a bell. This bell, as will be seen from the engraving, Fig. 1, is hung from the end of a lever which is supported in a raised position by resting on a knife edge formed at the side of a hollow spindle which rests on the top of a hollow fusible plug A, inserted in a casting which can be screwed into the top of the bearing. The plug A is made of hard lubricant, and on its melting the hollow plunger on the spindle c falls, thus lowering the bell so that its clapper is acted upon by a wooden striker fixed to the revolving shaft. When the plunger c falls the glass globe containing oil falls with it until the collar e of its mounting comes into contact with the tubular part b of the main casting. This arrests the further fall of the globe, and the plunger c continuing to fall, parts the conical joint shown, and allows any oil that may be in the glass globe to flow down at once through the holes d on to the bearing. In Fig. 2 the arrangement for discharging the oil just described is omitted, and the arrangement simply gives an alarm on the bearing heating and melting the plug A.

The third arrangement shown by Fig. 3 differs from the others inasmuch as no fusible plug is employed, but the alarm is brought into action by the heating of the bearing causing the expansion of mercury or other fluid confined in the chamber d, this expansion forcing up the plunger a and so depressing the bell. A modification of this arrangement has been designed by Mr. Alley as a "feeler" for use on the bearings of marine engine connecting rods or other moving parts. In this case the alarm bell would be fixed to the framing of the engine, and the end of the plunger c would be allowed to project through the cup f. When forced outwards by the expansion of the fluid this projecting part would come into contact with the bell striking it at each revolution. In such cases the confined fluid has an advantage over the composition plug inasmuch as it does not require to be renewed each time the apparatus is brought into action, and thus there is no necessity for stopping the engine.

Considering that numerous important fires in mills have originated in hot bearings, Mr. Alley's "feelers" are well deserving of the attention of millowners, and we hope to see them extensively used.

BLAST FURNACE CHARGING APPARATUS.

In the United States as in this country the advantages derived from working blast furnaces with closed tops are being largely recognised, and on page 97 we give illustrations showing an arrangement of charging apparatus, invented by Mr. P. L. Weimer, and manufactured by Messrs. Weimer and Birkenbine, blast furnace engineers, of Lebanon, Pennsylvania.

According to this plan the tunnel head of the furnace is fitted with the usual form of bell, hopper, and lip-ring, the lower part of the bell and the bottom of the lip-ring being turned off so as to make a tight joint. On the top of the hopper is placed an iron cover, provided with three or more openings (the engravings show three openings), which can be closed at will by sliding doors. The rod supporting the bell passes through the top of the cover, and is attached to one end of a beam, which is supported upon a casting of sufficient strength, combining two cylinders, one horizontal and the other vertical, with their necessary ports, &c. The piston in the horizontal cylinder is connected by means of piston and connecting rods with a revolving plate on top of the cover, to which the doors are attached. These doors are hung on hinges, so that in case of any excessive pressure they will open, or it may at some time be desired to lift one or the other of them. The piston in the vertical cylinder is connected by a piston rod with the end of the beam opposite that to which the bell is attached.

Fig. 1 on page 97 represents the bell closed and the hopper ready for its charge, which is supplied by means of the usual charging barrows dumped through the open doors. When the charge is to be dropped the attendant depresses the left-hand lever, shown in Fig. 1, which, admitting steam into the horizontal cylinder, causes the plate on top of the cover to revolve and carry the doors with it, thus closing the openings. A small safety valve placed on the cylinder prevents risk of damage by too sudden closing. When the doors are closed the right-hand lever, Fig. 1, is raised, which, by admitting steam into the vertical cylinder, drops the bell and its charge. By depressing the same lever the bell is raised again to its position, and the valve arrangement is such that the movement is under the easy control of the operator, who can bring the bell to its place as gently as he pleases. The screw on the rod supporting the bell admits of its exact regulation, and the swivels admit of perfectly free motion; the top of the cover acting as a guide.

When the bell is in place the left-hand lever, Fig. 1, is raised, which causes the doors to open. Fig. 2 is a view of the apparatus with the bell dropped and the doors closed; it also shows the opposite side of the supporting casting. The apparatus can be operated by steam, air, or water-power, and can readily be removed in case any repairs are necessary at the tunnel head. Special provisions are made to obviate difficulty when a bell falls into the furnace or accidents occur. The only gas which escapes is, obviously, so much as can be contained within the space between the bell and the cover—a very small amount. Mr. Weimer states that with the usual mode of dropping the bell a fair approximation of the daily waste of gases from a moderate sized furnace would be from 60,000 to 100,000 cubic feet, a quantity which is surely worth utilising. This apparatus also obviates the necessary changes in temperature and pressure, which must follow the opening of the full area of the tunnel head every few minutes. The arrangement we illustrate has, we understand, been applied to a number of furnaces in the United States.

NOTES FROM SOUTH YORKSHIRE.

Sheffield, Wednesday.

Reduction in the Price of Coal.—Yesterday many of the coalowners and merchants of the district lowered their prices by about 1s. to 1s. 6d. per ton. The demand has not for some time been at all up to what it usually is at this time of the year, so that the output is above the requirements of the market—hence the reduction. Coke, however, is unchanged at 18s. to 19s. for local and 22s. to 24s. Durham.

Proposed Reduction of Ironworkers' Wages.—Last week the puddlers and other first processes men at the works of John Brown and Company, and Charles Cammell and Com-

35

PHOTOMETER.

76

Here is also a photometer, or light-measuring apparatus, in reality a triple machine, so that three observers can measure the value of a sample of oil at once. The standard for measuring the value of oil for illuminating purposes is a certain amount of wax candle, burned in a given time; the candle is burned and weighed at the same time that the oil is also burned. The lamp and candle are placed at the opposite ends of a long wooden bar that is graduated, and carries a small sliding carriage; on the carriage are two small mirrors set at an obtuse angle to each other, and midway between them is a small screen of ground glass with a small spot in the centre, that is semi-transparent. Turning the screen directly towards one's self and looking on both sides of it, the reflection of the spot is seen near the centre of each mirror. The lamp and candle being provided with covers, pierced by small slits opening towards each other, and the room being darkened, the rays of light from both the lamp and the candle are allowed to fall upon the spot in the screen, in fact to meet there, and neutralize each other; then the observer slides the carriage along, until by the equality of the two images, as seen in the mirrors, the neutralization of the rays is seen to be perfect, and the graduated scale at that point shows the comparative illuminating power of the flame; the carriage of course being nearest to the weakest light, by the usual proportion of the square of the distances, which is accounted for in making the scale. The object and value of the experiment are apparent upon considering the number of the lighthouses, and the amount of oil consumed, making it essential to have the very best article the market can produce.

ELECTRIC FALL MACHINES.

1877

These are for demonstrating the laws of falling bodies. In one arrangement a brass ball is hung by a thread some height above the ground. Under it, at distance = 1, are two metallic balls connected with the poles of an electric machine; they are so far apart that a spark cannot pass between them, but if the suspended ball drop between them a spark will pass. Further down, at distance = 4, then = 9, etc., are similar pairs of balls. The thread of the suspended ball being burnt, the latter falls between the successive pairs, giving passage at each pair to the current, and simultaneously the spark in another part of the circuit strikes a revolving soot-blackened drum, making a mark. The distances between successive marks are found to be equal. In a second arrangement, there are two cylindrical conductors, insulated and vertical, with a metallic ball suspended between them at the top, hardly filling the interval, and sufficient to enable a spark to pass between the cylinders, which are connected with the poles of an induction (secondary) coil. One of the cylinders has a coating of soot-blackened paper. The thread is burnt, and the ball falls; sparks are made to pass at regular intervals of time, by means of clockwork, interrupting the battery current. Each spark leaves its mark on the blackened surface; and thus are shown the spaces passed over in equal times.—*M. Waldner.*

The Loffel Mechanical News. July 1, 1881.

There is a great difficulty in keeping coffee at its proper temperature throughout the day; overheating spoils its aroma, and underheating gives it a stale taste. M. Honore, a café proprietor, of Luneville, has invented a very simple apparatus to meet the difficulty. He immerses in the coffee a mercury thermometer, open above, and containing a float connected rigidly with a metallic needle, the other end of which moves on a dial. As the normal temperature of the coffee may vary between 88° and 95° C., the part of the dial between these terms is made of ebonite. Should the needle pass beyond them in either direction, electric contact is made and a bell is rung. In one case the heat requires to be intensified; in the other to be let down. The invention might be easily completed (says L'Electricita) by adapting an electro-magnet, which would close a gas-cock when there was too much heat and open it when there was not enough. A small jet might be kept constantly lit. It is further suggested that small electric lighting instruments might be substituted for matches in cafés.

34

36

TORPEDO IMPROVEMENTS.—The Whitehead or "fish" torpedo, which has cost this country a very large sum of money in order to possess its secret, and to perfect and manufacture it in large numbers, is the object of continual study and experiment, in the hope of further increasing its powers, and counteracting the various devices which have been suggested as expedient for resisting its attack. With the improvements contrived since it has been in the possession of the Government the torpedo can be set to run a straight course of a thousand yards under water, and explode on striking its object; it can be arranged so as to half-cock or full-cock its trigger when nearing the enemy's ship, to rise near the water-line or sink to the keel, as may be desired, and if it misses its aim it will release a safety-pin, and go quietly away, to be recovered at leisure. Its attack, however, could, it is thought, be effectually guarded against by surrounding the threatened ship with a strong net 40 feet or so from the hull, and it is to meet this difficulty that official research is now directed. It is the weakest point of the formidable fish that, being driven by an air-engine, the speed diminishes with the decreased pressure in the air-cylinders, and that, although a very high speed is ensured throughout the whole journey, the pace is lowest at the further end of the course. There does not seem any help for this, but various expedients are being tried to reduce the weight of the torpedo and thereby obtain increased velocity, and it is in contemplation to make a considerable diminution in the amount even of the charge. Recent experiments have proved that a few ounces of gun-cotton, when exploded in contact with an object, will exercise an effect far more destructive than a much larger quantity placed at a few yards distance, especially in water; and, provided the torpedo struck a fair blow on the side of the ship, it would matter little whether it contained 500 lb. of gun-cotton or only 50 lb., for either would burst the sides of the thickest armour afloat. What is wanted is a rate of speed which will tear through the enemy's network—a store of energy at the end of the race for another encounter.

TORPEDOES.

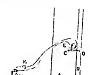
LIEUTENANT-COLONEL MARTIN, Box Grove, Guildford, late commanding 4th (King's Own) Royals, writes to *The Times* on the subject of an "International Anti-Torpedo Association," which, he states, he is about to set on foot. He says: "When explosive bullets and chain shot were invented, and actually used in war, nations unanimously agreed to discontinue their use, and prohibited their manufacture; yet explosive bullets and chain shot, it must be admitted, are harmless as compared with torpedoes. Poisoning is prohibited in war. Why not prohibit torpedoes, which are actually more subtle and deadly than poison, there being no antidote to or escape from them? For instance, were I allowed to fire from a mortar gutta-percha bags filled with strychnine and charged with a 'burster' and time-fuse to cause the bag to burst and scatter its diabolical contents over some obstinate city or fort which would not capitulate, this visitation would be far more merciful in its way towards the people of that city or fort than torpedoes would be against crews of ships, because strychnine could be seen, and avoided by flight, whereas, on the other hand, torpedoes secretly moored, or even fish torpedoes, insure complete, sudden, unexpected, and unavoidable destruction. Several clever artisans have already been killed by merely pumping compressed air into the tails of unloaded fish torpedoes. Had these torpedoes been loaded with gun-cotton for service on board ship, and even if one of them exploded from careless handling during action while compressed air was being applied to start it, or if by chance a shot or shell struck the ship at the time of starting a fish torpedo on its death track, the fearful consequences may be easily imagined. As a proof that governments appreciate the danger they incur by the use of torpedoes, I may here state it is well known that after the Austro-Italian wars all the picked-up torpedoes proved to be 'dummies.' It is our bounden duty to keep pace with other countries, but every one will admit that the sooner the International Anti-Torpedo Association has accomplished its task the better for humanity."

[28075.]—Electric Lock.—Perhaps the following simple method will suit "Ironmonger:"—Procure a bar of iron about 18in. × 2in. × ¾in.; fix this bar behind the door, so that it can be worked by a knob from the outside; about 9in. from one end cut a notch about ½in. broad and ½in. deep in the top edge of the bar, fix a piece of soft iron about ½in. square and 3in. long, made in the shape of a T, so that when the door is fastened by the bar it will drop into the notch and hold the bar fast; about ½in. above this

4/1

fix an electro-magnet, which must be connected with a battery in such a manner that the connection can be made in your office. Instantly connection is made the magnet will lift the piece of iron from the notch and the bar can then be moved by the knob from outside. On connection being broken the piece of iron would fall into the notch. Again, when the bar was replaced a bell might be fixed in office to be rung by the boy when he is ready to open the door. The following is a rough sketch of the bar, &c.—F. J. W.

[28075.]—Electric Lock.—I think the following plan would be found suitable: Let A be the door and B the post against which it closes. Have an ordinary latch, C D, and fix on it a piece of soft iron E. Fix an electro-magnet, F, on the door so that its ends come to about ⅛in. from the piece of soft iron, E.



The wires from the electro-magnet, F, are connected with the battery, H, but are interrupted at K by a knob-pushing arrangement. Now, when you press the knob, K, the circuit is completed, F becomes a magnet, and attracts E, drawing up the latch from the catch, D. I should advise you to buy a Leclanché battery. All the rest you can make yourself.—C. DETAILLE.

37

this means of overcoming the mischief which such an action might have cannot be too highly regarded.

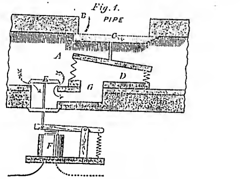
NEW APPLICATIONS OF ELECTRICITY TO ORGAN BUILDING.

A CONCERT organ has recently been erected in Chickering-hall, corner of Eighteenth-street and Fifth-avenue, in this city, which is remarkable for the numerous entirely novel and ingenious electrical and pneumatic inventions which enter into its construction. The instrument is one of considerable magnitude, having three manuals, a compass of 58 notes, 29 pedal notes, 33 stops, and the necessary couplers and mechanical accessories. So far as the location of its parts is concerned, it is really three organs in one; that is to say, a portion of the pipes are on one side of the stage, a portion are some 60 feet away on the other side, while a complete though small organ, used for echo effects, is placed on the roof of the hall, and about 175 feet distant from the single set of keyboards at which the entire apparatus is manipulated.

The portion of the instrument which is directly in rear of the keyboards is provided with pneumatic levers, so that the pressure on a key, instead of acting directly upon the valve of the pipe to be sounded, opens a valve which admits air into a small bellows. The latter, in its movements, actuates the pipe-valve, and thus performs the heavy work, so that the merest touch is sufficient to move the key. With the exception of this ingenious, pneumatic device, all the rest is directly mechanical, and, since it does not differ from the usual church-organ arrangements, needs no further reference. In the other two organs, however, are found the curious electro-pneumatic inventions which have seemingly revolutionized the art of organ building, for by their aid not only can new effects be produced, but one or a dozen organs can be played at once, and all their stops perfectly controlled, and this irrespective of whether they are located within ten feet or ten miles, or in fact any distance, from the player.

We propose to explain, by the aid of the annexed diagrams, first, how the pipes are sounded through pressing the keys, and, second, how the stops are manipulated. For the benefit of those unfamiliar with organs, it may be stated in advance that, by means of stops, air is admitted from the main bellows into any desired set or sets of pipes. Each set of pipes gives a different quality of tone, and thus the performer may select just such sounds (flute-like, trumpet-like, &c.) as best suit the character of the music. Having regulated his instrument by adjusting the stops, his fingers, by pressing the proper keys, open the valves leading to the individual pipes, and thus the instrument is played. In order to apply electricity to the object first mentioned above, it will be obvious that the keys must act exactly as do the keys of an ordinary telegraph instrument—that is, on being pressed down, they must establish a current which, passing over a connecting wire, actuates mechanism at a distance. This is precisely the case, so that the organist has no power to exert beyond the very light pressure necessary to so move the keys. Each key controls its circuit; and as the mechanism is the same for each, a description of one will suffice for all.

Fig. 1.



In the diagram, Fig. 1, A is a part of the air chamber, in which air, led by an air trunk from the air bellows, is kept compressed. B is the pipe corresponding to the key whose operation we are considering. There is an opening between the air chamber and pipe, closed, as shown by the valve, C. Attached to this valve is a small bellows, D. Through the bottom of the air chamber is another orifice, in which plays the double valve, E, the stem of which is continued downward, and is attached to the pivoted armature of the electro-magnet, F. Said armature is provided with a spiral spring, the effect of which is to hold it away from the magnet, and so to shut the lower part of valve, E, while holding the upper part open. This being the case, a portion of the compressed air in A will pass under the valve, but, being unable to

38 28

THE ELECTRIC CANDLE.

The value of electricity as a source of artificial light has always been recognized, and its utilization has frequently been attempted. The great obstacle, however, which has hitherto prevented the practical attainment of this object is the difficulty of subdividing an electric current, and pro-

No. 78. JUNE 30, 1877.

ducing a number of lights from one main source. This subdivision of the current, as it flows from the generator, has several times been attempted, and in some cases—experimentally, at least—it has been attended with success. The fine carbon points were, however, quickly consumed when burnt in contact with oxygen, and thin platinum wires melted as soon as they began to give a perfect light, and, so far as we are aware, no system of subdivision of electricity has come into practical operation.

About the first who attempted to solve the problem was, M. Lodyghin, of St. Petersburg, who, some few years since, used a vacuum, burning the carbon out of contact with the oxygen of the atmosphere. The details of his apparatus, however, were imperfectly worked out, and failure resulted.

M. Kosloff then took up M. Lodyghin's idea, and in time succeeded in producing an efficient means of subdividing the electric light. By forming the holders for the carbon points of a special metal, and producing the light in a vacuum lamp, excellent results were produced.

M. Kosloff's apparatus was exhibited in London in May, 1874, and some very successful trials were made with it, and reported upon by us at the time. It does not, however, appear that this invention went beyond the phase of experiment, at least in England, although it was an invention of great promise. Hence, wherever electricity has been utilized, as in lighthouses and for signalling or other purposes, the constant shortening of the carbon points by combustion has to be compensated for, and followed up by clockwork, so that the necessary distance between the points is preserved as nearly uniform as possible.

It has remained for another Russian man of science—M. Paul Jablochkoff, who was formerly in the Russian military service—to demonstrate in practice the feasibility of subdividing the electric current. He has worked out his results in the form of an electric candle, which governs the production of the electric light, and supersedes the ordinary clockwork arrangement. By it he has, moreover, demonstrated the possibility of obtaining several lights from a single source of electricity.

The first practical trial of this system was made two weeks ago at the Magasins du Louvre, and the experiments were attended with perfect success. The Marengo Hall was the apartment lighted, and six electric candles were sufficient to shed around a very bright light, which was softened by being transmitted through oval glass globes. Some idea of the comparative value of gas and the electric light under notice may be formed when we state that the Marengo Hall is ordinarily illuminated by means of one hundred argand gas burners of the largest size. The cause of the wide difference between this and other electric lights lies in the fact that electricity plays, so to speak, only a secondary part in producing the light. The light is principally the result of the combustion of the refracting material, which occupies in the electric candle the same position as does wax or tallow in ordinary candles.

The electric candle, as originally designed by M. Jablochkoff, consisted of what may be termed a double wick and a surrounding material. The wick consisted of two carbon points, about four inches long, embedded parallel to each other in an insulating substance, by which also they were separated from each other. This material, which was consumed as well as the double wick, was composed of several ingredients, forming a combination known only to the inventor. Each of the carbon points terminated at the bottom in a small metal tube into which the conducting wires were led. With these candles a series of experiments was some time since carried out by a War Office Committee of Royal Engineers at Chatham. It was then demonstrated as one result that the system gave fifty per cent. greater power of light than had ever before been obtained from any electric light. The next development of the electric candle by M. Jablochkoff was to denude it of its outer casing, leaving merely the double wick with a strip of the insulating compound between the carbon points, which terminated at the bottom in metallic tubes, as before. It was with the electric candle in this form that the hall at the Magasins du Louvre was illuminated, as previously stated. In either case only one electrical machine is needed to produce a number of lights. The positive and negative wires are led from the machine, and branch wires are simply conducted from them at the necessary points to the candles. In this way M. Jablochkoff succeeded in getting as many as eight candles to burn at the same time in the circuit of a single machine of the ordinary kind, with alternating currents.

Arrangements are being made in England to light up one of the East and West India Dock Company's docks in London upon M. Jablochkoff's system, so that the loading and unloading of ships may be carried on by night as well as by day when desirable. Experiments were to have been primarily made in order to test the system, but since the exhibition of the electric candle at the Louvre, M. Jablochkoff has still further improved his system, so that the experiments have been postponed for the completion of the details of the improvement. In the new form of candle the inventor dispenses with the carbon points which constituted the wick, and uses only the outer surrounding material answering to the tallow of an ordinary candle. We have already seen that this compound—to which M. Jablochkoff has given the name of "kaolin," which substance enters largely into its composition—consumes at the same rate as the carbon points. From this material alone M. Jablochkoff now produces results superior in many respects to those which he previously obtained. One point of superiority consists in the fact that he is now enabled to produce as many as fifty constant and uniform lights from a single machine of the ordinary kind, as was recently stated in a paper brought before the Academy of Sciences, in Paris, by M. Dumas. In short, M. Jablochkoff appears to have satisfactorily solved the question of dividing up the electric light by a method capable of practical application, of insuring perfect steadiness in the light so divided, and of distributing throughout a building lights of varying degrees of intensity. The results point to a very wide application of the system, which appears to possess special advantages for the lighting up of theatres and other large buildings.—*London Times.*

—A new pocket photometer has lately been described to the French Society of Photography, by M. Schutte. The instrument has exteriorly the form of a small telescope. Putting your eye to the narrow end, and, looking through at a luminous source, you see a small luminous circle, on which is detached some figure in black. On turning the wider part of the instrument, the more you advance in the series of numbers, the weaker is the light perceived; and, at length, it quite disappears. This effect is obtained by means of leaves of waxed paper, the number of which increases with the figures. Thus, it will be understood, that a weak luminous source does not allow one to see the same number as a strong one, and the variation between the figures is greater, the more difference there is in intensity. Thus one may be enabled to determine the proper time of exposure.

Jan 7

[20135.]—Torpedoes.—I forward a sketch of the Whitehead or fish torpedo. It is made of the same specific gravity as water, or nearly. It is constructed with four feathers along the side, and

May 77

terminates with a hoop or cone, which answers several purposes—viz., steers it, adds strength to the feathers, shields the screw, and concentrates the power for propulsion. If charged with compressed air from 3,000lb. to 3,500lb. per square inch, it has a range of 2,000 yards. It is passed through a tube in the bow of a vessel fitted up for the purpose. It can be set to any range, and taken alongside of a boat and liberated. A is the cone or hoop, A end view showing the three-bladed screw, B; the body is taper, B, showing section with feathers; the holes at C are where the air escapes after it has done its work on the turbine to drive the propeller; D are two lugs to support it in the tube and upon the guides from which it is passed; E is the shell for explosive material. If the ship is well trimmed that the torpedo passes out perfectly level it varies very little in its transit; but when the propelling power is exhausted it rises to the surface, and just shows a margin above water.—JACK OF ALL TRADES.

29

Comme on le voit par ce court exposé, Duchesne, de Boulogne, est peut-être de tous les médecins de cette époque, celui qui a le plus contribué aux progrès des sciences médicales. C'est par sa persévérance, par son admirable talent d'observateur, par son esprit patient et ingénieux, qu'il est arrivé à réaliser tous ces travaux. C'est également grâce aux moyens d'investigation que lui ont fourni les courants électriques, qu'il a pu enrichir la médecine de ces nombreuses découvertes, et mieux que tous les autres faits, l'histoire de ces recherches montrent l'importance de l'application des sciences physiques dans les sciences biologiques. Sans ce petit instrument qui donne des secousses musculaires, et qui n'est qu'une des formes les plus ordinaires de l'électricité, bien des points de la médecine seraient encore ignorés et obscurs. Ajoutons encore, que Duchesne était un homme plein d'aménité, travailleur. Il encourageait avec plaisir tous ceux qui voulaient suivre la même voie scientifique, et les aidait de ses conseils. Malgré la valeur incontestable de ses travaux, ni la Faculté, ni les Hôpitaux, ni l'Académie de Médecine, ne lui ont donné la moindre position officielle : Duchesne, de Boulogne, ne faisait partie que de la Société de médecine de Paris. Cet exemple est bien la meilleure critique de l'organisation officielle de notre enseignement supérieur.

Dr Onimus.

STATISTIQUE

DES DIVERSES APPLICATIONS DE L'ÉLECTRICITÉ D'APRÈS LES BREVETS D'INVENTION

La loi qui régit les brevets d'invention en France, comme les lois correspondantes des autres pays, en protégeant les inventeurs, les oblige, en retour de cette protection, à faire connaître loyalement et sans restrictions les découvertes qui sont le fruit de leur intelligence ou le résultat de leurs recherches. Les brevets d'invention ne sont donc pas seulement des titres légaux d'une durée temporaire, ils constituent en outre des documents servant à enregistrer à perpétuité et à divulguer les innovations et les perfectionnements enfantés par le génie humain, et que souvent la tradition serait impuissante à sauver de l'oubli. On peut dire des brevets qu'ils sont les archives de la civilisation industrielle.

Sans doute, on ne doit pas s'attendre à trouver dans chaque brevet la trace d'une idée neuve, voire même d'une amélioration. Mais il est certain que les brevets envisagés dans leur ensemble peuvent fournir les indications les plus précieuses pour étudier la marche du progrès dans chaque branche de l'industrie. Rien ne semble donc plus naturel que de soumettre les brevets à un dénombrement pour les classer par catégories, et former ainsi les éléments d'une statistique utile et même nécessaire, si l'on veut apprécier le rôle et l'influence des inventions industrielles dans le développement des besoins sociaux.

C'est à ce point de vue qu'il nous a paru intéressant de faire le relevé de tous les brevets qui ont été pris jusqu'à ce jour concernant l'électricité.

Le nombre de ces brevets s'élevait au 1er mai de cette année à un millier, chiffre rond. Mais dans ce chiffre ne sont compris que ceux qui se rapportent directement à l'électricité ou à ses applications; et il existe évidemment plusieurs autres brevets où l'électricité joue un rôle important, bien qu'elle ne figure pas dans la désignation de l'invention.

Les premiers brevets commencent à apparaître seulement dans l'année 1829. A cette époque on commençait à peine à connaître les découvertes d'Œrsted qui datent de 1819; celles d'Arago et d'Ampère, qui ont fondé l'électro-magnétisme, base des applications mécaniques de l'électricité, et notamment de la télégraphie électrique. Jusque-là, l'électricité statique et la pile de Volta avaient été peu utilisées industriellement, et par conséquent n'avaient pas donné lieu à la prise de brevets.

En suivant la marche des brevets concernant l'électricité, par année, on constate qu'elle progresse très-lentement jusqu'en 1852. Avant cette époque, le nombre annuel des brevets ne s'était jamais élevé à plus d'une douzaine, et, brusquement, il fait plus que doubler et atteint le chiffre vingt-sept. Si, dans les années précédentes, le nombre des brevets demeurait très-restreint, il est à remarquer pourtant que la liste emprunte un éclat tout particulier au nom des illustres inventeurs, tels que Morse, Bréguet, Caselli, etc., qui ont fait faire de si grands et si rapides progrès à la science électrique, si nouvelle encore.

A partir de 1860, le nombre des brevets s'augmente encore, et atteint son maximum en 1867. En cette dernière année, on en compte soixante-huit, et ce chiffre n'a pas été dépassé depuis, ni même atteint. Pourtant la différence, quant aux années suivantes, n'est pas considérable; elle est même presque insignifiante. Les deux années fatales 1870 et 1871, elles-mêmes, quoiqu'à moitié perdues par suite de tant de cruels événements, ne voient pas s'abaisser sensiblement le chiffre des brevets qui ont pour moyen ou pour but l'électricité. Tout au contraire, dans les trois années qui suivirent il y eut une certaine décroissance, puisque les brevets pris en 1872 sont au nombre de soixante-six, et ne sont plus que de quarante-sept en 1873. Néanmoins, depuis ce temps, la tendance à l'accroissement, lent mais régulier, n'a cessé de se manifester, et on peut prévoir que la présente année comptera environ soixante brevets.

Le rapport du nombre des brevets d'électricité au nombre total de tous les brevets pris annuellement, demeure à peu près constant, et dans les six dernières années il y a eu environ un brevet d'invention électrique pour cent brevets touchant toutes les autres formes de l'activité humaine. Cette proportionnalité indique la part relativement très-grande que prend l'électricité dans les inventions et les perfectionnements modernes.

Plus d'un tiers de tous ces brevets ont pour objet la télégraphie, ce qui prouve, sans qu'on ait d'ailleurs à s'en étonner, combien cette application de l'électricité, la plus merveilleuse, la plus utile, a engendré

40

Blasting by Electricity. 77

Blasting by electricity, one of the latest practical developments of science, is being generally utilized. The advantages are great saving of explosives, safety, and protection of life, economy of capital and time, and overcoming obstacles that nothing else will, such as firing under any quantity of water; sinking or driving in soft sandstone, granite splitting, rooting up trees, blasting slag, etc. On Saturday, June 16, a gigantic explosion was arranged in the granite quarries of Messrs. Ellis and Everard, at Bardon Hill, near Leicester, by Messrs. Aikin and John Harris, of Nobel's Explosive Company; six holes being put in, averaging a depth of 20 feet, each hole being charged with 15 lbs. of dynamite, and exploded with Capt. Brain's electric fuses. The machine used to fire them was Capt. Brain's American Improved, a most compact and simple article, being only some 14 lbs. in weight, which may be used by the ordinary working men, giving an electric spark 2 inches in length. The firing of these six holes had a most marvelous effect, the whole quarry having the appearance of being rent as by an earthquake. Huge blocks of granite were tumbled out, and upon careful examination and measurement it was computed that 14,500 tons had been dislodged and thrown into the bottom of the quarry. This practical demonstration of the effect of simultaneous blasting with a powerful explosive in connection with quarry works was most satisfactory to the proprietors and other gentlemen present, it being generally acknowledged that such successful results had never been known in the district before.

The Electric Blasting Apparatus Company, Cinderford, Gloucestershire, have also just very successfully laid down a set of blasting apparatus at South Kirkby Colliery, near Pontefract, where shafts are being sunk to a depth of 700 yards. The advantages of the system are so apparent in collieries already using this apparatus in the district that its use is becoming more general. At the Houghton Main Colliery, near Barnsley, two 15 feet shafts are each firing 10 holes at once, and raising 70 tons of *débris* from a shot, an increase of 50 tons a blast on the old system—a practical demonstration of the great advantages of simultaneous blasting.—*Mining Journal.*

WANTED—TORPEDO DEFENCES.

Mr. E. J. Reed, late Chief Naval Constructor of the British Navy, in a recent lecture before the Society of Arts, took occasion to express an opinion which, we think, every one who has given any thought to the method of waging future maritime wars has already more or less definitely reached. Coming from an engineer who has been so closely identified with the building of the ironclad navy of Great Britain, the views enunciated will assume greater force. They could not be more radical or more direct. Mr. Reed says, in substance, simply that, until a way of protecting vessels from the effects of torpedoes is invented, ironclad ships, notwithstanding their 24 inch armor and 100 ton guns, are anachronisms, and that their construction is waste of time and money. "Neither the suspension of chain nets, nor additional bulkhead divisions in ordinary forms of ships, will be a sufficient, nor anything like a sufficient, defence against this deadly submarine instrument of attack. The naval Whitehead torpedo delivers a most terrible blow; it moves for the space of some hundreds of yards with a speed double that of the fastest ironclads; its path is so sure and true that at that distance a second torpedo can be made to pass through the hole which the first has made; and whereas it has been assumed that, in ordinary conditions of weather and naval warfare under steam, a ship could not have more than a few feet of her depth below water attacked, the torpedo has the whole immersed bottom of the ship exposed to its assaults." Mr. Reed goes on to say that the days of war ships, more or less long and narrow, and with deep bottoms of thin iron containing the steam boilers and powder magazines, are numbered. He advises his government to reconsider its intention of beginning the building of a vessel of the Agamemnon class; and finally he concludes that modern naval necessities are "first, the construction of our large ships on principles which make them as little destructible by torpedoes as by guns, which I believe to be quite possible; and secondly, the building of all our other war ships of small and handy types." By the latter he means small vessels which can be manœuvred with sufficient rapidity to avoid torpedoes.

Mr. Reed unfortunately fails to mention the plan for protecting ships against torpedoes, the knowledge of which he implies that he possesses. It will be seen, however, that in this opinion a total reconstruction of the English navy is necessary, and that consequently the enormous sums of money which have been expended on its development are entirely thrown away. This is not cheering intelligence to the British taxpayer; and we doubt whether its purport will be acquiesced in until inventors, the world over, confess themselves vanquished by the problem of devising an efficient system of torpedo guard. So long as enormously heavy artillery is to be used, vessels must be built both capable of carrying the guns and likewise capable of resisting them. Already it is contemplated to build cannon which will dwarf the 100 ton gun; and the English iron founders, on the other hand, promise 40 inch rolled plates. If war ships must carry such loads of metal as these, it is difficult to see how they can be built light enough to dodge torpedoes. There is certainly little to be gained by building vessels possessing the latter advantage, if at the same time they are to be rendered easily vulnerable by heavy guns.

We agree with Mr. Reed in the belief that it is possible to protect large vessels against torpedoes, although we have no especial project to propose. The subject is one which we would particularly commend to the attention of inventors. It is obvious that the necessary protections can be obtained in two ways: first, by devices outside or extraneous to the vessel, and second, by modification of the construction of the ship itself. The simplest outside device is the torpedo netting constantly used by our vessels during the war. This is simply a network of chain or rope supported on booms at some distance around the ship and extending down into the water deep enough to guard the entire bottom. To prevent the access of torpedo launches, the ship may be surrounded by heavy spars also attached to the booms, and from these chain nets, as already described, may depend. These devices are obviously of little use or altogether impracticable when the vessel is in motion. To avoid stationary torpedoes anchored in channels, ships have used forked catchers protruding from the cutwater, to grasp and cause the explosion of the obstruction. Rafts pushed in front of ordinary vessels likewise serve a similar end. Under the second plan, war ships are built in watertight compartments. The Inflexible, for example, has 127 such sections. Or, as in the case of Admiral Porter's boat, the Alarm, there is a double hull with the space between divided up, while the entire hold of the ship may, through the watertight bulkheads which cross it, likewise be converted into separate sections. A torpedo, it is supposed, might injure a few compartments, while those still staunch would perhaps float the vessel. With iron ships there is not much surplus of buoyancy, however, and the racking effect of a blast might cause results much worse than the direct injury to the compartments immediately adjacent. Probably the means of defence nearest to security, lie first in keeping the vessel constantly

under steam and under control, and second in the electric light which reveals the approach of an enemy by night. But the circumstances of weather or of locality may prevent the rapid manœuvring of the ship, and a fog may render the electric beam useless; while there is no safeguard against the unseen approach of the submarine torpedo of the Ericsson, Lay, or Whitehead type.

The conditions of the problem need no especial explanation. It is simply a question of how to render a ship's bottom invulnerable, not merely to the explosion of the torpedo itself but to that shock *plus* the energy of the ramming blow delivered by the sharp bow of a heavy torpedo boat. An invention of this kind would be immensely valuable to every naval power, and would insure fame and fortune for its originator.

TORPEDOES.

BY S. OAKUMA.

The development of submarine warfare has been so rapid of late that it is hardly possible to foretell what potent influence it may have on the war now being waged in Eastern Europe. While England, France, Italy, and in fact nearly all the European naval powers, have been building huge engines of war, of a tonnage, armor, and artillery never heard of before, the torpedo has been gradually perfected, and threatens, at least under many circumstances, to neutralize them. A torpedo may be regarded as a gun which dispenses with a gun carriage, and which, without the vast and expensive agency of a great ship, inflicts as formidable a blow as that of the heaviest artillery.

The original inventor was David Bushnell, born at Westbrook, Connecticut, 1742. He not only devised a torpedo, but also a submarine rowing boat, intended to convey it to the bottom of the vessel to be attacked. His practical experiments, however, which he was enabled to carry out with the assistance of the private purse of George Washington, did not prove successful; and the invention sank into oblivion until the commencement of the present century, when Robert Fulton, an American sojourning in France, offered a similar one to the French Government. After considerable parleying, it was rejected, and Fulton sold his secret to the British Admiralty for $75,000. The so-called Catamaran Expedition, an attempt to destroy the French line-of-battle ships and transports off Boulogne, turning out a failure, Fulton returned to the United States, and, during the war of 1812, tried in vain to blow up several of the English blockaders. The rage of the British commanders knew no bounds and the proceedings were termed "unchristian," "the invention of a fiend," etc. Cousin John Bull has a frightfully short memory at times!

In 1829, Colonel Samuel Colt commenced experiments with a submarine torpedo exploded by a galvano electric battery; and after many disappointments, he succeeded on October 18, 1842, in destroying the brig Volta in New York harbor, in the presence of 40,000 excited spectators. So far only vessels at anchor had been attacked; but on April 10, 1843, Colt blew up a brig of 500 tons under sail on the Potomac river, he himself being the operator, and at the time at Alexandria, five miles distant from the explosion.

The first European government to adopt the invention was Austria, who laid down a perfect electric torpedo net for the defence of Venice. Russia followed suit, and during the Crimean war protected the entrance of Cronstadt as well as that of Sebastopol harbor by an improved system of ground torpedoes, which kept the English fleet at a respectful distance. The American civil war for the first time clearly demonstrated the tremendous effect of the invention, and at the same time changed its character from a purely defensive to an offensive weapon. Galled by the soon-established superiority of the United States navy, which gradually sealed up all the important Southern ports, the Confederate Government organized a special torpedo service corps; and after sinking torpedoes in every available approach, they proceeded to build small steamers constructed to carry spar torpedoes. These torpedo boats, with an easily comprehensible Biblical allusion, were called "Davids," and were in several instances used with as much pluck and perseverance as terrible effect. The United States soon imitated the David, and in 1864 the late Commander Cushing, U.S.N., succeeded in destroying the Confederate ram Albemarle, lying at anchor in the James river. Since then the electric apparatus for torpedoes and the torpedo itself have been vastly improved; and numerous new inventions have been introduced, all of which, however, may be classed under the following five heads: Ground torpedoes, spar torpedoes, Harvey (towing) torpedoes, Whitehead (fish) torpedoes, and the Lay torpedo.

GROUND TORPEDOES.

The ground torpedo is a sort of sunken mine, exploding either by contact or by electricity. If these are judiciously laid down around a harbor or anchorage, the approach of hostile ships may be rendered impracticable, provided always they are protected by shore batteries or armed ships to prevent removal. Every channel may be barred by these hidden mines; and they may be made so powerful that any ship under which they explode is sure to become hopelessly disabled. They are fastened to and held in their positions either by anchors or by stockades. The bursting charge consists of gunpowder, gun cotton, or dynamite; and the case or shell is either made of iron or wood; in Charleston harbor, old steam boilers were frequently used.

SPAR TORPEDOES.

The spar torpedo is fastened to the end of a spar from 15 to 38 feet long, carried in a boat, no matter how small, and explodes also either by electricity or contact. A most remarkable experiment was recently made at Cherbourg, France, with spar torpedoes, carried by a little vessel called the Thorneycroft, which was almost submarine. We illustrated this invention on pp. 236 and 246 of our current volume. A very small part of it was above water, but it was of sufficient strength to carry engines and two lateen sails, and it was worked by a lieutenant, two engineers, and a pilot. The French Admiral had two disabled ships in succession towed out to sea at a speed of 14 knots an hour. The Thorneycroft, however, was able to go at the rate of 16 knots an hour, a rate not attained by any vessel in the squadron. She very soon caught up with her prey, delivered her blow with a spar torpedo, which projected from her bow, and rebounded. A rent as big as a house was made in the side of the ship attacked, and she sank at once. The Thorneycroft only spun round and round for a few moments, and then returned uninjured to the squadron, from which she had started. A vessel of this kind is scarcely discernible in the water; even if she were detected, she is so small that it would be difficult to hit her; and half a dozen Thorneycrofts attacking a large vessel would be a most dangerous foe. Their expense is quite trifling compared with that of great ships of war; they can be multiplied indefinitely, and they can be carried on board other ships and be launched from them as occasion may require. The Italian Government has already carried out this idea in the construction of her formidable new ironclads Dandolo and Duilio. These vessels are fitted in their sterns with a sort of armored dry dock, harboring a small torpedo steamer. As soon as the services of the latter are required, the dry dock is filled with water and opened, and the little craft rushes out at the enemy, returning to her safe berth after her mission has been fulfilled. Admiral Porter's torpedo vessel Alarm, also recently illustrated by us, is fitted with spar torpedoes, both for bow and beam; but the torpedo generally supplied to all the cruisers of the United States is the

HARVEY (TOWING) TORPEDO.

Invented by an English officer in 1862, it was soon adopted by nearly all the other navies, and probably will be exclusively used in general actions at sea as least liable to injure a friendly vessel in the *mêlée*. The Harvey torpedo is towed upon the surface of the water by a wire rope towline from a derrick end of the yard arm over or against the enemy; and just before reaching the ship to be destroyed this towline is slackened, and the torpedo, being heavier than water, dives under it. When in this position the explosion is effected by means of a mechanical firing bolt striking down upon a pin as soon as certain levers of the torpedo come into contact with the bottom of the target. This torpedo can also be made to explode by electricity. Two different forms are used for starboard and port.

WHITEHEAD (FISH) TORPEDOES.

This invention is the secret and the property of the British Admiralty, but the following details have leaked out: These torpedoes resemble in shape a cigar, pointed at both ends, and are 18 feet long by two feet in diameter. The inside is divided in three different compartments: First, the head, which contains a charge of 350 lbs. of gun cotton and the pistol or detonator to explode it; secondly, the balance chamber, which contains a contrivance for setting it so as to remain at any depth at which it is wished to travel under the water line; and lastly, the air chamber, which contains the engines and the compressed air to drive them. The after end supports the screws—a right and a left handed—which propel the torpedo and are made of the finest steel. The air chamber is tested to the pressure of 1,200 lbs. on the square inch, although for service it is only loaded to 800 lbs. The Whitehead torpedo can be made to go at the rate of 20 knots for 1,000 yards, and at any depth that is desired from 1 foot to 30 feet. It can be set to explode either on striking an object or at any particular distance under 1,000 yards—in artillery language, either by a percussion or a time fuse. It can also be set so that, if it misses the object aimed at, it will go to the bottom and explode at half cock or come to the top on half cock so as to be recovered, as it has buoyancy enough just to float on the surface of the water when not in motion. It is fired from what is called an impulse tube, which, out of a frame fitted to a port, discharges the torpedo into the water. It can be fired above the water, but will at once go to the depth it is set for, and then go straight to the object, no matter how fast the ship from which it is discharged is going, or how fast the object aimed at may be sailing or steaming. In fact, it seems that it can do anything but speak. It is calculated to make a hole on bursting of 70 foot area, and there is no doubt that, if one of them hits a ship of any sort or description at present on the water, she must at once proceed to the bottom. It is evident that by this means a comparatively feeble ship, if only able to approach within 1,000 yards of a large one, can discharge a deadly flight of unseen projectiles at her, and at night such an attack will probably be wholly unsuspected and scarcely open to resistance, as the vessel fired against will be positively unaware of the attack until she is blown up. The newly invented electric light from the tops is a great help to the party attacked; but if three or four boats of great speed attack a vessel from different points of the compass, and if they are commanded by smart officers, nothing that she can do will save her from being hit by one or more of them. There is no doubt whatever that this torpedo is the most formidable weapon of modern naval warfare.

THE LAY TORPEDO.

Properly speaking, the invention of Mr. Lay, purchased by the United States Government, is not a torpedo, but a very ingeniously devised submarine torpedo boat fitted with a spar torpedo. This boat has the advantage of not requiring any crew on board, but in other particulars is capable of great improvements. The motive power consists of an engine driven by carbonic acid gas and a screw propeller. The boat is entirely submerged, and is steered and in all other respects controlled by means of an electric battery on shore, connected with her by a cable which is coiled up in her hold and pays out as she moves away. Her location is indicated above the surface of the water by a flag, so as to enable the operator to direct her course. The greatest defect of the Lay torpedo is want of speed. The United States Government stipulated for a speed of 9 statute miles per hour, but the maximum speed actually attained at the late trial trip, when it was steered by Lieutenant R. B. Bradford, U.S.N., showed only an average of 6·60 miles per hour, so that a ship attacked would only have to lower her boats and let them row between the approaching torpedo and the shore, and cut the cable, which would leave the torpedo at their mercy. The defence of ships against torpedo attacks of all kinds is at present very imperfectly developed, principally owing to the fact that the offensive qualities of any weapon must first be learned before effectual means of defence can be devised; and as actual warfare only can give a correct idea of the former, we are, no doubt, on the eve of very startling events, which may entirely revolutionize and change every recognized principle of naval tactics.

The great anxiety felt in England for the future safety and efficiency of the British navy, on account of torpedoes, is shown by the attempted formation of an International Torpedo Association, which Lieutenant Colonel Martin, of Boxgrove, Guildford, late commanding 4th (the King's own) Royals, is about to set on foot. He says in his programme: "When explosive bullets and chain shot were invented and actually used in war, nations unanimously agreed to discontinue their use and prohibit their manufacture; yet explosive bullets and chain shot, it must be admitted, are harmless as compared with torpedoes. Poisoning is prohibited in war. Why not prohibit torpedoes, which are actually more subtle and deadly than poison, there being no antidote to escape from them? For instance, were I allowed to fire (from a mortar) gutta percha bags filled with strychnine and charged with a bursting and time fuse to cause the bag to burst and scatter its diabolical contents over some obstinate city or fort which would not capitulate, this visitation would be far more merciful in its way towards the people of that city or fort than torpedoes would be against crews of ships, because the strychnine could be seen and avoided by flight; whereas, on the other hand, torpedoes secretly moored, or even fish torpedoes, insure complete, sudden, unexpected, and unavoidable destruction. Several clever artisans have already been killed by merely pumping compressed air into the tails of unloaded fish torpedoes. Had these torpedoes been loaded with gun cotton for service on board ship, and even if one of them exploded from careless handling during action while compressed air was being supplied to start it, or if by chance a shot or shell struck the ship at the time of starting a fish torpedo on its death track, the fearful consequences may be easily imagined. As a proof that governments appreciate the danger they incur by the use of torpedoes, I may here state that it is well known that, after the Austro-Italian war, all the picked-up torpedoes proved to be dummies. It is our bounden duty to keep pace with other countries, but every one will admit that the sooner the 'International Anti-Torpedo Association has accomplished its task, the better for the cause of humanity!"

It is much to be feared that other nations will prefer to take a different view of the case, and continue to consider torpedoes a cheap and effective counterpoise to the costly and powerful English ironclads.

77

Application of Electricity in Dyeing.

According to the *Bulletin de la Société Industrielle de Mulhouse*, Goppelsroeder has observed that if an electric current is passed through aniline dye baths decoloration ensues, with formation of colorless salts of leukaniline. If yarns or cloths are steeped in the liquid they absorb it, and on subsequent exposure to the air they become colored, just like the goods drawn out of an indigo vat and exposed to the air. The colors thus obtained are said to be faster than those produced by the ordinary method. Whether this principle of dyeing will prove practically useful remains to be seen.

June

TORPEDO PRACTICE. 77

THE actual use of torpedoes as engines of war, though theoretically most valuable both for attack and defence, has drawbacks which are worth considering. We may refer, by way of evidence, to Captain Scott's remark on Mr. Donaldson's paper in regard to the Whitehead torpedoes (see IRON, p. 654)—that every ship of war carrying a supply of these missiles, carries a terrible and novel source of danger to herself. Again, in the present war, it is reported that, with the aid of skilled divers, torpedoes can be successfully disarmed. It is not difficult, therefore, to understand that the manufacture of torpedoes is one thing, but that their successful use is totally different. For coast protection there are two classes of torpedoes, the mechanical and the electric. At the present time, except in peculiar circumstances, the mechanical torpedo presents so many disadvantages—not the least of which is that its success depends a great deal on accident, and is, consequently, very problematical—that it may almost be excluded from consideration. Yet, when mention is made of the use of torpedoes during the present war on the Danube or elsewhere, it would not do to assume that the mechanical torpedo is discarded. This weapon is useful enough if it is properly planted, if it is properly made, if a great many other considerations have been carefully noted, and if, finally, luck is on its side. But, once laid down, it cannot be tested, nor can it be manœuvred in any way. It is as likely to injure friend as foe, and is not unlikely to be found perfectly harmless to both. In fact, it is a two-edged weapon, which is as dangerous as it is useful, and it proved its terrible unsteadfastness in a variety of ways during the American War. Now, when it is reported that the Turks are prepared to render Russian torpedoes inoperative, reference is evidently made to this class of weapon, which can easily be ruined without risk of serious danger. The electric torpedo is, however, a more formidable weapon, and can hardly be destroyed or ruined, except by accident, or by taking advantage of extraordinary carelessness on the part of those who are interested in its safety. The deadly nature of this weapon may be realised by remembering that the operator is on shore, undisturbed, with plenty of time for quiet and accurate calculation, and dependent only on nerve for the success of his torpedo. But, and this "but" is very large, the use of electricity, especially in a case like this, where the results are so serious, requires a large exercise of dexterity and delicacy. The smallest deviation from the prescribed course may lead to an awful disaster, and a slight want of nerve may send a friend instead of an enemy to the bottom. In fact, the position of the operator is not unlike that of a pointsman or signalman on a railway. Captain Fisher places this in a strong but intelligible light in his remark that "when that most trying time comes in which the utter destruction of an enemy's ship may rest solely on the operator, he will be able to act instantaneously, without hesitation. There is no time to think then. The enemy, if he is wise, will be forcing his passage at his utmost speed—one instant he is in danger from the torpedo, the next he may be safe—with the exception perhaps of a good shaking." His subsequent remark is worthy of being inscribed in letters of gold in every battery and every man-of-war:—"The great secret of the successful management of torpedoes will be found to consist in paying the utmost attention to apparently trifling precautions, and in trusting no one."

In the use of torpedoes, or in their actual application in time of war, one of the most important lessons to be learnt is their planting. Great judgment and care are essential here, and it forms naturally an important feature in all courses of torpedo instruction. In referring to the difficulties of this operation, Captain Fisher has pointed out that it is of the utmost importance in laying down a torpedo to insure the preservation of its exact position; to avoid any chance of a fracture of the insulated wire through twisting; to calculate accurately the exact height and force of the tide, so as not to expose the torpedo at low water, nor make it imperative at high; and to consider eddies, currents, winds, the action of spring tides, and any other exceptional points in the channel under protection. Position also requires great consideration and experience; for it is quite possible to lay down scores of torpedoes which would be perfectly useless. For instance, it is essential to plant them at such a distance from the line of coast under protection as to prevent ships from coming sufficiently near to use their guns effectively. It is also important to plant them like lettuces or cabbages, sufficiently far apart from one another not to interfere with independent action. Reference has been made recently to the valuable aid to be derived from the *camera obscura*; but this instrument, useful as it is, has been rather overrated, for its accuracy in daytime is difficult to insure except in peculiar circumstances, and at night it would naturally be useless.

But while the difficulty in using the electrical torpedo is chiefly technical or mechanical, and can be overcome by practice, the treatment of torpedoes to be used at sea, whether in the "spur" or "Whitehead" form, calls not only for technical skill and dexterity, but for personal qualities of the highest order. The "spur" torpedo is intended to be used in the new Thorneycroft boats, such as the *Lightning*. The object of these boats is, by the attainment of a speed of twenty or twenty-five miles an hour, to attack any man-of-war by coming up with it, launching against it a torpedo, and then running away again. Simple as this operation may seem, it is attended with such manifest danger as to prove that special qualities of nerve and readiness are requisite. To use a torpedo in this way efficiently, it is important to be very careful both as to the place and mode of using it. As failure will, almost inevitably, prove fatal, constant practice is necessary to attain the necessary proficiency. In fact, to be successful demands on the part of the officer chosen for this work an amount of nerve and of delicate judgment not exceeded in any other warlike operation. The great recommendation about this mode of using torpedoes is that, if successful, its success is undoubted. The case of the *Housatonic*, mentioned by Mr. Donaldson at the United Service Institution, is a case in point. But precision in attack is absolutely essential. It is quite possible, as has been proved by experiment, to explode a torpedo harmlessly, although in actual contact with a ship's side. In one case the charge was submerged only six feet, and although the charge consisted of 50lb. of powder, no vital injury was done. To quote Captain Fisher on this point—"The vertical effect of a submarine charge, no matter at what depth, is much greater than that in any other direction; this is but natural. The explosion is dammed up laterally, stopped by the bottom, reacted upon laterally, reacted upon by the bottom; so it is evident the greatest effect must take place in a vertical direction. This principle should always be borne in mind when endeavouring to attack an enemy's vessel with outrigger torpedo boats." He quotes an instance, the case of the *Albemarle*, where "the torpedo was submerged ten feet, and exploded under an overhanging portion of her stern, which, though several feet from, yet was virtually over, the torpedo."

Although this subject admits of much elaboration, and a great deal remains to be said about the special danger of the Whitehead torpedo, not only in its actual use, but in the mere fact of carrying such a destructive weapon in a man-of-war, we have said enough to show that there are two sides to the torpedo question. The torpedo is a very double-edged tool, and, valuable as its powers are for attack, its value depends mainly on the exercise of exceptional and high qualities.—*The Times.*

Captain Morgan Singer, of the *Vesuvius*, torpedo ship, has been carrying out a series of experiments in the capacious repairing basin at Portsmouth, with the object of discovering the best means of defending ships against the attack of the Whitehead torpedo. Up to the present time the ingenuity of the naval architect has been mainly exercised to protect ships against the entrance of shot and shell; and while for this purpose he has gone on increasing the thickness of the side armour, the bottom of the ship, against which the attack of the torpedo is directed, remains to almost its original weakness. How to protect the hull against both the gun and the torpedo and at the same time preserve the seaworthiness of the ship is one of the many problems in naval construction which have yet to be solved. In the meantime two methods of protection against torpedoes are proposed—viz., the employment of fast "satellites" to ward off and attack the torpedo boats before they can get within range, and the erection of crinoline frames around the ships themselves, by means of which the rush of the projectile would be arrested before striking the hull. Both devices have their disadvantages. The general use of patrolling craft would immensely complicate the exigencies of an engagement by provoking a number of subsidiary battles around the main action; besides, the champions of these small craft seem to forget the all-important fact that in the next naval engagement the principal antagonists would themselves use the torpedo. Hence, even with the adoption of an auxiliary fleet, it is essential that our ships of war should be fitted with some defence against this terrible submarine engine. The torpedo net will necessarily impede the way and obstruct the manœuvring of an ironclad, and, such being the case, the object of Captain Singer has been to ascertain the form of crinoline which would oppose the least resistance to the water and the most resistance to the torpedo. Various forms of nets, composed of alternate lines of bars and chains, have been tried, but the size and power of the missile have been so increased of late that it has been found that the torpedo nets of the *Thunderer* afford little or no protection. Last week a chain net, formed of chains 5-16ths of an inch thick, was easily perforated by the Whitehead. The great fault of the nets is their extreme rigidity, which opposes a solid wall to the impact of the torpedo, and the bars are consequently snapped. After many trials, however, very successful results have been obtained from a wire grummet, matting, composed of wire strands about half an inch in thickness rove into open meshes. It possesses considerable flexibility, and, as it yields when struck, the force of the torpedo is not suddenly, but gradually, arrested, and as it loses its momentum it is thrown back by the recoil of the mat. During the experiments a torpedo thus forced back twirled its tail off without inflicting any injury to the matting. This is the nearest approach to perfection which has yet been attained.

June 77

Some New Uses of Electricity. 77

1st. The galvanic chair, to prevent joggling in schools.

2d. The torpedo battery, to prevent fainting fits among girls, and shock at once any fainted female (for which all other remedies fail) into perfect consciousness.

3d. Electric whips, to tickle horses by slight shocks, and thus cause them to run, or stop them at once by the parlyzing effect of a strong discharge.

4th. Electric hair-dressing machine, causing the hair to stand up perpendicularly. The ladies liked it at first, but found out that when any young man came in contact with their electrified hair, a crackling explosion followed, and was the means of frightening away some timid young fellows, one of whom said that he "didn't want any girl of his who put nitro-glycerin in her hair."

5th. The latest is the electric dining machine, invented by a French physician for the benefit of a patient who could not swallow. He filled his mouth with food and then gave a downward shock through his jaws and throat, when all went down with the velocity of the electric current—that is, at the rate of 4,000 miles per second. This man, it is reported, has since dined daily by help of electricity, going through the whole bill of fare of an exquisite French dinner, including the delicacies of the season—wine, coffee, ice-cream, Charlotte-Russe, etc., in 1 minute and 14 seconds.

The *New York Times* recommends this system highly to the American business men who have no time to spare, and now waste as much as 12 or 15 minutes between soup and toothpicks. The time so wasted while eating is estimated to be worth $300 per year for each, and for a city like New York, alone would amount to some hundred millions of dollars per year. If the whole country coöperated, estimating the money-making population at ten millions, we could pay the whole national debt in a very few years, if men would only agree to follow the advice and swallow their food by the help of electricity.

FACTORY NOTES.

ELECTRIC CLOCKS FOR GLASGOW.—The corporation of Glasgow have agreed to fit up thirteen electric clocks, in order to remove a grievance regarding the disparity of time indicated by the present public clocks. The clocks, which are to have large white faces with distinct black figures, will be pretty equally distributed over the city in prominent places, where they are likely to be readily seen during the day, and where there is sufficient light to render them visible at night.

[13020.]—Electric Clock Pendulum (Bain's).—As an accompaniment to my sketch of electric pendulum, page 611, No. 650, Vol. XXV., I inclose sketch of the break, which is a very important part of the clock. A, a square-shaped ivory bar, about 4in. long; *g g*, two small strips of gold plate, thickness of threepenny piece; platinum might do nearly as well. H H, two brass plates exactly similar to the gold ones, and fixed in the ivory bar close as possible to the gold strips without touching them. S, sliding rod of light wire, having two leg-pieces, L L, of gold to slide freely over the gold and brass plates. L a, end view of gold legs, L L. M M, two brass

77

pins on slider; these pins being struck with the pin, P, on pendulum staff by each vibration, when the pendulum swings to the left it will shunt the slider's legs so that both cover the gold strips which are shown shaded, and the circuit is then complete; the pendulum, on its return journey to the right, will again cut off the current by throwing the right-hand leg, L, on to the brass plate again, so that it only obtains its power whilst journeying from left to right until the slider is struck, when the current is disestablished. Should the pendulum by increased activity of the battery swing too far to the left, it will carry the slider off the left-hand gold strip, consequently deriving no impulse for the next swing. It will, therefore, be seen that to a very great extent the pendulum is its own regulator. If great care is used in the construction of such an electric pendulum, it will go for years by a plate of zinc about 2ft. square, with a little rough carbon embedded in the damp soil.—ALFRED CROFTS, Dover.

ELECTRICITY IN WAR

THE important *rôle* played by electricity in modern warfare affords an excellent example of the influence which science has of late exerted in naval and military affairs. It is no isolated example of scientific warfare that we have here to deal with, for the electric fluid has in a great measure changed our whole practice of war, and bids fair to revolutionise it still more in the future. Every soldier or sailor, if he desires to make his mark, must be something of an electrician, for there seems to be no limit to the useful applications of the galvanic spark in battle. Broadly, we may divide these applications under three heads; namely, the employment of electricity for signalling, for the explosion of charges, and lastly, for illumination, both for the purposes of attack or defence, it being a difficult matter to decide in which connection the electric spark fulfils the most important duty.

To begin with the telegraph. All will agree that it is well-nigh impossible to overrate the advantages which this rapid means of communication gives to the general, in these days, when the line of battle sometimes extends for a dozen miles. Let the commander occupy the most central position, a long time must elapse before his aides-de-camp can communicate with one wing or the other. Assisted by the electric telegraph, however, the general is as close to his subordinates as if he were within shouting distance. Even a brigade of horse artillery, or a cavalry division advancing at a gallop, can carry its telegraph equipment with it, the operators accompanying a flying column of this nature with but very little difficulty. The wire drums are started off at a gallop, the cable being unwound as the carts proceed, and a sergeant on horseback with a "sounder" to his ear, in connection with one end of the wire, receives the general's commands as soon almost as they are spoken. The movement countermanded or a retreat ordered, the cable is again wound up as readily as it was laid down, and the telegraphers make good their return with the rest of the troops. Where ordinary movements are executed, use is of course made of the telegraph wagon, a comfortable little office on wheels, furnished with all things necessary for the receipt and despatch of messages, but this convenience is naturally out of place where a rapid change of front, or some speedy flank movement has to be executed.

Coming next to the explosion of charges by means of the electric spark, we enter upon a phase of war-science which bids fair to grow to infinite proportions. Both Franklin and Priestley suggested the employment of electricity in this connection more than a hundred years ago, but it is very recently indeed that we have been in a position to make proper use of this valuable agent as a means of firing charges at a distance. In fact, at the present moment we have by no means exhausted research in this direction, and we find scientific soldiers and sailors still at variance with one another as to the best plan of using the electric current for firing purposes. One of the first applications made of the subtle fluid was in the removal of the wreck of the *Royal George*, at Spithead, nearly fifty years ago, when the explosion of the charges was brought about by what is termed a wire-fuse, or in other words a short piece of platinum thread stretched between two copper wires. The platinum bridge having less conducting power than the copper wires, presents a considerable amount of resistance to any current of electricity that passes, and, in doing this, becomes so heated, as to be capable of igniting any particles of gunpowder in contact with it. A wire-fuse of this description has simply to be placed in the middle of a charge, and if then a current of electricity is passed from a battery along the wire in connection with the fuse, instantaneous ignition is the result. This simple method of firing charges under water was a vast improvement over the old one in use by our engineers, which consisted in leading up a metal pipe from the charge to the surface of the water; the outlet of the pipe was placed as far as possible from the charge beneath the water, and then a ladle full of red hot shot was emptied down it, and so reached the gunpowder below, which thereupon exploded if the iron fragments had not become too cool in transit.

But for many purposes the wire-fuse is ill-adapted to the military and naval services. A voltaic battery is necessary to evolve the low-tension electricity required to yield sufficient resistance and heat, and such a battery made up of metal plates, and involving the use of acids, is an awkward apparatus to carry in the field. Already in 1853, this fact seems to have occurred to a Spanish officer, Col. Verdu, who determined to see what could be done in the way of exploding gunpowder by a spark, or in other words, by high tension electricity. Aided by a Ruhmkorff coil he succeeded in firing half-a-dozen charges simultaneously, and although the discharge was sometimes a matter of considerable uncertainty, to Verdu certainly belongs the credit of having been the first soldier to apply electricity in this way to the firing of one or more mines. Wheatstone and Abel followed in Verdu's footsteps, and while the former directed his attention to the construction of a frictional apparatus of a portable nature, which should be suitable for military use, the latter busied himself in the preparation of a fuse inclosing a compound more delicately explosive than gunpowder, a fuse, by the way, which still retains an important place among our warlike stores.

It was in the China war of 1860 that we first find an electric firing apparatus forming part of an army equipment. In this case the outfit was of a somewhat clumsy nature. A conveyance, in shape and size much resembling a baker's barrow, contained a monster horse-shoe magnet, and it was the sudden disruption of its armature from this magnet which generated the spark to fire the fuse. A few years afterwards, this ponderous conveyance gave place to a neat little mahogany box about a foot cube, which contained half a dozen small but powerful magnets, in the field of which the armatures were made to revolve with exceeding celerity; and it is by means of such an apparatus that to-day we are enabled to fire a score of charges at a time, the wires branching off from the instrument to a distance of a hundred yards or more. But, nevertheless, we have yet to devise, it seems, an efficient exploding apparatus capable of igniting both low and high tension electric fuses.

As everybody knows, it is by reason of electricity being employed to fire explosive charges that torpedo warfare has

4½0

INTESTINAL OBSTRUCTION TREATED BY ELECTRICITY.

Sept 77

M. Giommi (*Centralblatt*) gives an instance of the benefits of electricity in intestinal obstruction in the case of a man, aged fifty-one, who, up to the time of his illness, had always been strong and well. He had had complete obstruction for some weeks, and was almost moribund when the idea struck M. Giommi that the cause of the evil lay in atony of the walls of the bowel. He accordingly applied a strong induced current several times during two days, each time for ten or fifteen minutes. One electrode was introduced into the rectum and the other applied to the abdominal wall, in the course of the transverse colon. The result was marvelous; copious stools followed the free escape of gas, and after a few days the patient left, quite well.

Metals as Photometers.—The discovery of Siemens that light influences the capacity of selenium to conduct electricity, and which we have mentioned before, has now been applied to the construction of a new photometer, or instrument to measure the intensity of light. It has also been discovered that tellurium (a semi-metallic substance similar to selenium) partakes of the same capacity; while, finally, M. Boernstein, of Heidelberg, announces that he has discovered that it is the same with platinum, gold, and silver, and probably all the metals in some small degree. 78

Sept 13/78

Some extraordinary statements have been going the round of the papers relating to an instrument called the telegastrograph, by which, through the aid of electric currents, the flavour of any food or liquor can be transmitted by wire to any distance, and the sensation of eating or drinking conveyed by merely placing the end of the wire between the teeth. This wonderful device is the invention of a member of the staff of the *Melbourne Age*, and that paper contains an account of certain experiments in which several scientific men in the colony are alleged to have taken part. Our contemporary does not supply any details of the machine, perhaps wisely, but we learn that it has a receiver, and there is an electro-magnetic battery capable of being turned on. We are gravely informed by our contemporary that the observers at the different stations having taken the wires between their teeth, the alcoholic essence of a large quantity of sherry was "sent along the wires," and the thirty-six "observers" received the impression of having each consumed a bottle of sherry and bitters. It should be noted that only one bottle of sherry with a wineglassful of bitters was poured into the receiver, and yet every sign of incipient intoxication was produced. The flavour of various articles of food was transmitted in this manner, and on one occasion, when the soup was too hot, the wires were very rapidly drawn from the mouths of the guests at Government House. "Every bubble on every glass of champagne poured into the receiver was faithfully imprinted on the palates of the observers." We suppose that our Australian contemporary considers it has done a very clever thing, but it is doubtful whether Mr. Ellery and Baron von Mueller will feel gratified in finding themselves made partly responsible for the statements of a writer who is a very second-rate Gulliver indeed.

FRENCH TORPEDO EXPERIMENTS.

We publish engravings, showing the effect of a torpedo explosion directed against the Bayonnaise, an old wooden French frigate of about 2,000 tons. The experiments, which terminated in the practical destruction of the vessel, took place during February and March last off Cherbourg. On the 3d of March a torpedo charged with 33 lb. of damp guncotton, and carried at the end of a steel spar about 40 ft. in length, was exploded against the side of the ship at a depth of about 8¼ ft. below the surface of the water. The launch carrying the spar was, as will be remembered, one supplied to the French Government by Messrs. Thornycroft & Co., and it attacked the Bayonnaise at a speed of about 14 knots per hour, the frigate itself being towed by a steamer at a rate of about 6 knots per hour. Just before the moment of striking it was found necessary to reduce the speed of the launch. The explosion was followed by a shock, and a large wave, which flooded the launch and drove it back for a considerable distance. The damage done to the Bayonnaise was, as will be seen from the engravings, of such a nature as to have sent her to the bottom immediately, had not the precaution been previously taken of loading her with empty casks. She was shortly after towed into dock for inspection.—*Engineering*.

Engraving on Glass by Electricity.

Decr 78

M. Planté, the inventor of secondary batteries by means of which a large quantity of electricity may be accumulated, has just discovered an excellent means of engraving on glass. Having remarked that a glass tube traversed by a platinum wire serving as electrode to a powerful voltaic current was instantaneously spread out in the form of a cone or funnel, in the midst of an alkaline solution contained in a voltameter, he made a series of experiments to determine what alkaline solution required the least electric force for devitrification. He therefore thought out the following process, which has given some remarkable results:

The surface of a plate of glass is covered with a concentrated solution of nitrate of potash, by simply pouring the liquid over the plate laid horizontally in a shallow saucer. Then into the liquid which covers the plate of glass is introduced a horizontal platinum wire, connected at one end with the edge of the glass plate and at the other with the poles of a secondary battery of 50 or 60 elements. Now taking in the hand the other electrode, (formed of a platinum wire surrounded everywhere except at its extremity with an insulating sheath), the surface of the immersed glass is touched with it at the points where it is wished to engrave. Wherever the electrode touches, a luminous furrow is produced; and, whatever be the rapidity with which the writing or drawing is done, the traces made are found clearly engraved on the glass. If the writing or drawing be done slowly, the traces are deeply engraved; as to their width, that depends on the diameter of the wire serving as electrode; if it be sharply pointed the traces may be made of exceeding fineness. Either electrode may be engraved with, but the negative requires a weaker current.

EFFECTS OF TORPEDOES ON THE HULLS OF VESSELS.

48

ELECTRIC SIGNAL FOR DIVERS. 77

We subjoin an illustration of a neat arrangement of electric signalling apparatus, designed by Mr. Prothero, for the use of divers, and patented by him. The invention relates to the means provided to enable the diver to transmit signals through insulated wires imbedded in the ordinary "life line" to a telegraph instrument at the surface, this instrument being of any kind which may be considered most suitable. The fact of the insulated wires being imbedded in the life line dispenses with any extra ropes, while it also leaves the life line free to be used for signalling in the ordinary way if by way of any mischance anything should go wrong with the electrical apparatus.

Referring to our engraving, A is a portion of the diver's life line extending to the vessel above, having enclosed in it, or entwined with it, two insulating conducting wires B and C. These wires terminate in springs D and E, having on them contact faces d and e, which may be platinized in the usual manner. The ends of the springs D and E engage in a recess in a sliding piece of vulcanite or other non-conducting material F, both ends of which project through the sides of a tube G, in which the spring contacts are enclosed.

Over the tube G is fixed an external tube H of caoutchouc or other flexible waterproof fabric, which covers the ends of the sliding piece F. In the ordinary or normal position of the springs the two contact faces d and e remain apart, so that no electricity can pass from one of the two wires B and C to the other. But when the diver, by pressing with his thumb on either of the projecting ends of the slide F, pushes either of the springs D and E toward the other, then the two faces d and e are brought into contact, and an electrical circuit through the wires B and C is completed. By the pressure of the water the outer tube H will be more or less collapsed, but as the pressure acts equally on both ends of the slide F no contact will be made except when it is pressed in either direction by hand. By maintaining contact for a shorter or longer time signals of the ordinary Morse character can be readily transmitted. The ring at the lower end of the apparatus is secured to the diver's waist by a belt or cord. Intelligent communication from an unencumbered diver necessarily facilitates any submarine undertaking, as in most cases where force is required it can be applied from above under the direction of the diver from below. The safety of the diver is also more assured in intricate positions, where by the old method his signals would be indistinct.—*Engineering.*

9

Use of Electricity in War. 78

In the art of war many scientific discoveries have been utilized, originally expected to extend the blessings of peace. Steam-power, the servant of trade, by diminishing distance and multiplying carrying power, also accelerates the speed of armies and augments the number and the force of destructive weapons, missiles, and engines. In like manner electricity, which annihilates space, not only gives wings to messages and counsels of peace, but brings into instantaneous communication the field of battle, the commander's tent, and the council-chamber where sovereign and ministers debate on policy, and condenses into weeks the consultations and the operations that, without this aid, would be the work of years. But this is only a small part of the duty which electricity seems destined to discharge in the wars of the future. Its most effective work will be the firing of submerged and invisible torpedoes, as far removed from the actual touch of those who use them as from the knowledge of those for whose destruction they are to be employed.

Electricity is as Protean as life itself; its beneficent form of to-day is constantly found to neutralize its noxious form of yesterday. The fitness of the electric light to circumvent the torpedo has engaged the experimental efforts of military scientists for some time past; and, judging from what is known of the recent practice in Europe, those efforts have led to a very appreciable success. The electric light apparatus which has been fitted up on board the new French war-ship Temeraire was brought into play, and the effect was such that no hostile vessel could have approached the illuminated ship within two miles without being seen. The results of the general adoption of this light, supposing it can be continuously relied upon, must go far to destroy the mysterious terror which at present surrounds the torpedo. Had the Temeraire been in the midst of foes on the occasion of the experiment, it would not have been possible for a torpedo-boat or ship to come near enough to discharge a moving torpedo without herself becoming a conspicuous mark for the Temeraire's guns. Add to this the use of the light in revealing stationary torpedoes planted under the sea, and we may safely congratulate ourselves upon our command over this manifestation of the electric force, and in regard to which our knowledge is daily increasing.

49

[Franklin Journal.]

THE ELECTRIC REGISTER AND KOENIG'S TUNING FORKS.

Nov 77

By LeR. O. Cooley, Ph. D.

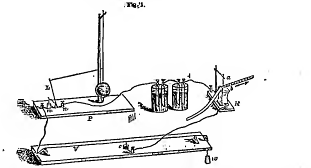
The application of electricity to register rapid vibrations was first made in 1868.* In that year I succeeded in obtaining a direct registry of the vibrations for all the intervals of of three successive octaves on a piano.† The wire was made to open and close a battery circuit in which an electro-magnet was placed, whose armature carried a stile, and, responding to the alternate efforts of the electric pulses and an opposing spring, flew back and forth in unison with the vibrating wire, and left a dot for each vibration on a strip of moving paper.

But the motions of an armature are too sluggish to keep pace with vibrations beyond a certain degree of rapidity; hence, the electro-magnetic method was speedily abandoned, and an electro-chemical registry substituted. "The requirements are: first, a steady stream of electricity from a powerful battery; second, means by which the vibrating body may open and close this electric circuit; and third, a rapid motion of chemically-prepared paper, through which the electricity is passing."‡

In the instrument first constructed, a fine copper wire, forming one electrode of the battery, was rapidly drawn along over the surface of a strip of tin-foil forming the other. A strip of tissue paper moistened with acidulated water, lay upon the tin-foil; upon it the moving wire constantly pressed, and every electric pulse traversing the paper left a velvety black stain upon the foil beneath. The vibrations in any measured period of time were thus revealed in a series of dots easily counted and permanent in the highest degree; records made then are as distinct to-day.

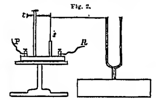
With this instrument the laws of vibration were demonstrated by an almost unerring registry in several courses of lectures, yet certain difficulties in manipulation forbade the expectation that it would become generally useful. By changing the form of the apparatus and perfecting the method, however, the electro-chemical registry became, it seems to me, a matter of comparative ease, enabling one to study phenomena depending on rapidity of vibration, with the precision attained by actual count. Whenever the vibration is of amplitude sufficient to open and close an electric circuit, an *autograph* of vibrating body will be the given in dots to be counted at leisure, and representing its rate within very narrow limits of error.

Fig. 1.



The accompanying cut represents the apparatus, arranged for the study of vibrating wires. The wire, *V*, a time measurer, *P*, and the register, *R*, are included in the same battery circuit. The wire is enabled to open and close the circuit by means of a fine steel needle, fixed to its middle point, beneath which is a cup of mercury, *c*, the surface of which is so nearly in contact with the point at rest that every vibration of the wire will immerse it in the liquid metal. With good mercury, the needle being a substance

Fig. 2.



not easily amalgamated and the surface of the mercury covered with alcohol to prevent oxidation, when once adjusted, little attention is needed afterward. Clean mercury may be substituted from time to time, and the needle may, if necessary, be cleaned by nitric acid.

For the measurement of time a pendulum is employed, which holds the circuit during the time of one beat. The arrangement for this purpose is represented at *P*. A slender fibre is fastened to the pendulum-rod, and thence reaches over to the upper end of a light bent lever, *L*. This lever moves freely, and is in conducting communication with a binding post, *n*. Beneath the lower end of the lever is a mercury cup, *m*, in metallic connection with another binding post. When the heavy pendulum is at rest, the weight of the lever keeps the fibre tense, and the mercury surface is so adjusted as to be exactly in contact with the point of the lever, a most vital adjustment, but one very easily made. It will be seen that the pendulum, when vibrating, must compel the lower end of the lever to be alternately in and out of the mercury during the exact time of one vibration.

The record of the vibrating wire is made in the register, *R*. A metallic point, *a*, presses upon a strip of chemically prepared paper, which runs over a platinum surface *b*. The pen and the platinum beneath are each provided with a binding post, by which it can be made a part of the circuit. The paper may be drawn through by the hand of the operator, the more swiftly as the vibrations are more rapid.

Let the circuit be continuously closed while the paper is in motion, and a continuous colored line will be traced by the pen, *a*; but let the wire vibrate, and electric pulses in unison with it will traverse the paper, leaving a series of dots instead. If the pendulum be at the same time in motion, the pulses can traverse the paper only while the lever, *L*, is in the mercury, and hence a *group* of dots on the paper will represent the vibrations of the wire in the unit of time.

Various electrolytes may be used in the preparation of the paper. A strong solution of potassic iodide, mixed with a small proportion of starch, is very sensitive and easily managed. A strip of paper, strong, thin, with a smooth surface—strips cut from a sheet of book-paper of good quality, not over thick, are excellent—is *moistened* with this mixture. If too wet the dots will run together, if too dry the electricity will not traverse the paper; the strip should be moistened uniformly, but not wet. The record is written by a platinum pen, *a*, in dots of a reddish-brown color. Let it be at once washed in a stream of water, and the expected blue color takes the place of the brown; the fluid is at the same time washed from the paper, leaving the record in a condition to be more permanent.

Or, saturate the paper with a mixture of potassic ferrocyanide and nitric acid, made as follows: To four parts of a saturated cold solution of ferrocyanide, add one part of dilute nitric acid—one ounce acid to five of water. If the color of the mixture is decidedly blue, too much acid has been used; if no hint of blue appears, too little. With this fluid the pen, *a*, should be of copper, and the record consists of brownish-red dots of cupric ferrocyanide. Let the paper be washed to remove the excess of fluid, and the record may be preserved. This substance is less sensitive than the iodide, and not so pleasant to work with, but the dots are more permanent. Records made a year ago can be counted still.

In experiments with tuning forks, the vibrations may open and close the circuit by means of a solid break-circuit represented in Fig. 2. From the prong of the fork a silk fibre stretches across to a slender vertical spring, *s*, fixed at the lower end, while its upper end rests against the end of a set screw, *t*. The two surfaces in contact are platinized. The spring is slightly bent, and the set screw, pressing against its upper end, holds it in constant tension, and thus forbids it vibrating, except in unison with the fork. Every vibration of the prong is transmitted by the fibre, and compels the spring away from contact with the screw. Putting this break-circuit in place of the monocord, represented in Fig. 1, between the pendulum, *P*, and the register, *R*, the vibrations of the fork record themselves upon the moving paper.

Noticing that the accuracy of Koenig's tuning forks is questioned by Mr. Ellis (*Nature*, xvi. p. 85), I fancied that the testimony of this method would not be without interest. Seizing the earliest opportunity, therefore, I submitted the *Ut₃* fork, bearing Koenig's monogram, to careful examination. The pendulum was accurately adjusted to hold the circuit one-half a second. The iodide-starch solution, with a battery of ten Bunsen's immersion cells, was used. Fifteen perfectly distinct and easily counted records were taken. Every one of these autographs was found to consist of 128 dots, representing 128 complete vibrations per half second, 256 per second, or 512 according to the French notation.

But the instrument cannot record fractions of a vibration; on the other hand, no complete vibration can escape its registry. Evidently when the rate of the fork is any whole number of complete vibrations, that number must be recorded. Exactly 128 vibrations, for example, would yield invariably 128 dots; 129 would yield 129 dots invariably; but 128 and a fraction vibrations would yield 128 dots in some experiments, and 129 in others, and in this case the mean experiments would be a close approximation to the exact value of the fraction.

Now in the experiments with the *Ut₃* fork the autograph *invariably* consisted of 128 dots, declaring the rate of the fork to be 256 complete vibrations per second, testifying to the exactness of Koenig's stamp.

ON ELECTRICITY IN DYEING.

March — By M. L'Abbé Vassart. 78

In dyeworks, the electric light is likely to render particular services as a light enabling the dyer by night, or in cloudy weather, to continue work which requires an exact appreciation of shades.

In the first attempts made at Roubaix, in the dyeworks of MM. Motte and Meillassoux, the same gradations of color and varieties of tone were recognized as in the daylight. All the dyers present agreed that matching of shades was perfectly practicable. A machine was fitted up at the works of Hannart Brothers, at Wasquehal, and has been in use every evening during the last winter.

It has been found practicable to dye by the electric light, greens, blues, and pearl grays, the quantity of the latter shade turned out having greatly increased since the introduction of the Gramme machine.

Another 300-burner Gramme machine has been fitted up at M. Gaydet's, at Roubaix, and has been in use most of the winter. It has been found that the electric light enables them to dye all shades to pattern except grays obtained by different methods, that is, when the red, the blue, and the yellow serving to produce them are not of the same nature.

But the electro-dynamic machine, so particularly advantageous in dyeing as a substitute for daylight, may also be capable of other applications in this branch of industry.

If we seek to explain the phenomena which occur in the bleaching of vegetable fibers, we cannot fail to perceive that at the foundation of all these procedures, however different in appearance, such as exposure on grass, bleaching with chlorine, with the hypochlorites, the manganates and permanganates, bichrome, and sulphuric acid, etc., there is one action in common, that of ozone.

Further, a great number of the artificial coloring matters are obtained by the oxidation of aniline, or its derivatives, by means of bichrome, chlorate of potash, arsenic acid, etc., and aniline black has been already produced directly by passing an electric current through the solution of a salt of aniline.

As the dynamo-electric machines have become economical sources of electricity, could they not produce ozone, or active oxygen, under conditions available in the arts?

Would it not be possible to regulate its action for bleaching fibers, and to take advantage of its remarkable properties in the preparation of some of these colors?—*Soc. Industr. du Nord de la France.*

Last year M. Grandeau made some interesting experiments with regard to the influence of electricity of the atmosphere on the nutrition of plants. He has more recently shown that atmospheric electricity affects very distinctly the phenomena of flowering and fructification. He worked with tobacco plants. The influence revealed itself in retardation of the flowering, and in the number of flowers formed about 50 per cent. more in the one case than in the other; also in the increase of the number of capsules of the fruit, and of the weight of the seed. Torpedo Telegraph Posts.—This term is applied to certain posts in Australia, which, we are informed, are "by an arrangement of supplementary currents" caused to communicate a severe shock to any one meddling with them. The unexpected punishment, attributed to supernatural power, which fell upon certain natives in the vicinity of McDonald Peak, when they attempted to cut the wire, had the effect of deterring other tribes from in any way damaging the Australian trans-continental line, the total length of which is about 2100 miles. Aug 23 '81

TORPEDO DEFENCE.

... 1 represents an imaginary harbor defended by torpedoes, the presumed width of the navigable channel being about one mile, and the mouth of the harbor itself, say, two miles. The line of torpedoes marked 1, 2, 3, are placed across the entrance at a distance of from two to three miles from the town; each line consists of seven torpedoes, each of which should contain a charge of 500 lb. of compressed gun-cotton, and be placed so as to converge on one signalling or converging station; of course this station only becomes a necessity when it is desired that the torpedoes in question be so arranged as to allow of their being exploded either by contact or from the shore by observation. The firing and converging stations are connected by a four-core electric cable, one conductor for each line of charges, and the other for telegraphing. The telescopic arcs A A A, shown at the converging station, are each provided with a single fixed telescope which commands one of the lines of mines; while those shown at the firing station, and marked B B B, are provided with telescopes that are capable of being revolved on their axis by means of a wheel and pinion arrangement, operated by a small mill-headed screw; each of these arcs are provided with seven sighting pieces—as described in a previous article—one sighting piece to each torpedo, fixed in a position corresponding to the position of the said torpedo as indicated by the telescope during the operation of mooring, and are connected so that one arc commands one particular line, and is in connexion with that line only; each arc at the firing station marked respectively 1, 2, and 3, being connected electrically with the arc at the converging station bearing that particular number, so as to include each individual line in a separate circuit, and thereby render firing by observation practicable. Each arc, both at the firing and converging station, is provided with keys for closing at will any particular circuit.

A signalling and shutter apparatus C with seven indicators—also described in a previous article—is attached to each telescopic arc at the firing station, and in connexion with the same individual line of torpedoes.

One battery of a hundred cells—modified Leclanché—is placed at the firing station, and is connected one pole to earth and the other to the firing terminal on the shutter and signalling and apparatus; but although attached to the apparatus it has no connection with the torpedo wires until one of the indicators fall. The dropping of the indicator arm may be effected either by the simultaneous action of the observers at the two stations, or by a vessel striking the circuit-closer in connexion with and floating above the torpedo. A signalling battery of two cells is also connected with the shutter and signalling apparatus, the mechanism of which is so arranged as to permit of the current charging all the conductors connected with it, yet no perceptible part must pass to earth without the circuit-closer being struck, when the full force of the current would instantly circulate, and trip the indicator arm belonging to the circuit closer struck, thereby switching in the firing battery current, and so explode the annexed charge. This system of firing may be in operation both night and day, but firing by observation can only be carried out in clear weather, when the approaching vessel could be clearly discernible with the telescopes of the firing and converging stations. Supposing an enemy's vessel were seen advancing in the line of torpedoes, but still outside the furthest line; the moment she covers one of the torpedoes, as observed through the telescope at the firing station, which must be moved rapidly from one to the other of the fixed sights that indicate the position of several of the mines, as often as the vessel changes its course, closing at the same time the key corresponding to the sight on which the telescope rests, and keeping them closed so long as she

remains covering them. But the observer at the converging station would wait until the vessel came on his line, closing his key only when she was crossing; and if she did not cover any torpedo in passing, the operator at the firing station watching would have no key down, and consequently no torpedo would be fired. As in this case she would be passing through the space between two torpedoes, and advancing on the second line, the key of the second line would then be closed at the converging station, the effect of which would be the completion of the electrical circuit, providing the operator at the firing station had compressed the key corresponding to one of the charges situated in the second line, thereby tripping the indicator belonging to the torpedo named, switching in the firing battery, and so exploding the mine, the two observers simply acting the part of the circuit-closer when struck. Should the vessel, however, strike the circuit-closer before both keys are closed the explosion would be brought about independent of the operators, so that both systems of firing are in operation at one and the same time, each entirely independent of the other.

The channel is also guarded by a system of electro-contact torpedoes placed a mile or so in advance of the outer line of large torpedoes. In our diagram each of the two lines of torpedoes is shown connected with the firing station by means of two single core cables, but it is also proposed to employ a four-cored cable running from the firing station, and terminating in a junction box, adjacent to the intended moorings, from which the branch cables, to which are connected the several short cables leading the charges, would extend; the remaining two cores being intended, one as a reserve in case it should be required at any time to throw out another line of torpedoes, and the other for establishing telegraphic communication between guard boats and the firing station during the night and in foggy weather. One great advantage in employing a vanguard of electro-contact torpedoes is that they save the necessity of expending so large a charge as 500 lb. of gun-cotton against minor vessels for the destruction of which a lesser charge would suffice.

A series of mechanical torpedoes are also shown guarding the flank of the electrical system, to which for this purpose they form valuable adjuncts. In the navigable channel, however, no torpedoes are employed save what are in connection with the shore, as it is absolutely imperative that they should be capable of being rendered safe for the passage of friendly vessels, and this can obviously only be effected by running the cables to the firing station and connecting or disconnecting them at will with the firing battery.

Referring to the diagram under discussion, Y and Z are two strongly fortified positions from which the electrical torpedoes are controlled. At the converging station Z are three fixed telescopes A A A, one to each line of mines, and a Morse telegraphing instrument for sending and receiving messages to and from the firing station; while at the firing station Y are three telescopic firing arcs B B B, each provided with seven sights corresponding to the seven charges of one particular line, one arc, as at the converging station, serving for each line; three shutter signalling and firing apparatus C C C connected with the firing arcs and with the cables in the manner shown on the diagram, four or seven strand copper wire insulated to five-sixteenths of an inch with india-rubber being usually employed for this purpose; a battery D of a hundred modified Leclanché cells; two cells E, Daniell's or medium size, ordinary Leclanché for signalling, one well-appointed "test table" with the necessary battery, five firing keys F F F F F, one test battery with galvanometer complete, one ordinary galvanometer, one frictional-electrical machine, one magnetic exploder, one magneto-electrical machine, one box of selected tools, two signalling lamps (Walker's patent), for each of which must be provided the following list of articles:

2 retorts.	1 oil lamp (reading).
1 wash bottle.	3 yards india-rubber tubing.
1 gas bag.	1 wrench.
1 pressure bag.	1 stove.
1 pair of lamp scissors.	1 case of potash.
1 box of lime pencils.	1 case of spirits.

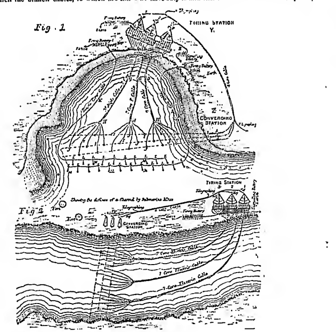
One portable tool chest containing the necessary tools for adjusting circuit-closers, etc., including one small plumber's stove, one soldering iron, one bottle of spirits of salts, a few sticks of solder, one small box of india-rubber solution, two rolls of india-rubber tape, one pair of pliers, and one hand knife, and, say, half a dozen military telegraph sounders. Referring again to our illustration, G G G are seven-core multiple cables, H H H are multiple junction boxes, I I I are single-core cables, J J J torpedoes, K K are also single-core cables, L L L T junction boxes, M M M electro-contact torpedoes, and N N N are mechanical torpedoes. The single-core cables K K may be connected to the large firing battery or to independent batteries according as the operator in charge may deem best. We doubt not but it will be more convenient to substitute for the two cables K K, one four-core cable and junction box, as before alluded to, especially if they are to be placed at any considerable distance from the firing station.

Fig. 2 illustrates the defence of a navigable channel, heavy ground charges only being employed, arranged to be fired either by contact or by observation; the general arrangement is precisely the same as in the diagram just described, and need not therefore be reexplained.

The instruments, etc., represented in the diagrams have been drawn to an exaggerated scale for the purpose of rendering the explanation more lucid.

In concluding this article on moored or fixed torpedoes, we have only to add that those interested in the torpedo question will now be in a position to judge of the possible efficiency of the approved appliances of to-day, and to see how needless are the fears expressed by sensational alarmists as to the presumable fate of our ironclad fleet in the maritime wars of the future. We do not, be it understood, wish to deteriorate in any degree from the merits of torpedo defence, or to underrate their value as obstructive agents; indeed we can unhesitatingly assert our belief that even should an enemy succeed in clearing a passage through them without any considerable loss to themselves—and we should certainly be disable if we pretended to think that anything but the grossest carelessness on the part of the invaders could lose them a single vessel—the delay necessarily caused would more than compensate for the outlay expended on them.

There are doubtless many ways by which an intelligent commander could force a passage through even the most formidable lines of these submarine obstructions, without any very considerable danger to his ship. It will be sufficient, however, for our present purpose to call attention to three methods, which are as follows: First, the sending down of divers to search for and sever the connecting cables; secondly, the sending out of small craft, under cover of darkness, to grapple for and raise the torpedoes bodily from their anchorage; and, thirdly, the projecting of a guard of Bessemer steel wire, or other material, some 40 ft. or 50 ft. in front of the vessel's prow, supporting it, if necessary, with buoys; by this means the circuit-closer would be struck, the circuit closed, and the mine exploded, before the vessel was near enough to be anything more than severely shaken.—*Engineering.*



TORPEDO DEFENCE.

RECENT TORPEDO EXPERIMENTS IN ENGLAND.

In England at the present moment the most active preparations for a prospective war with Russia are going on, and so far as naval operations are concerned the torpedo system is likely to be brought into more extensive use than ever before.

Recently a visit was made to Portsmouth Dockyard by the Speaker and some hundred other members of Parliament, entirely unofficial, the visitors having been invited by Lord Charles Beresford, M.P., Commander of H. M. S. Thunderer. Our cut and these particulars are from the London *Graphic*. Traveling from Victoria Station by special train, the party were received at Watering Island Jetty by Admiral Foley, Chief Constructor Robinson, and other officials. After crossing the dockyard in some open railway trucks drawn by a dockyard locomotive, they went successively on board the Inflexible, the Dreadnought, and the Thunderer, all turret ships of the latest type. The first-named of these vessels, about the stability of which there has been so much controversy, will probably be completed within the year. Her tonnage is 11,406, her horse-power 8,000, and she will throw about twice the weight of metal of any other English ship. The Dreadnought is much nearer to completion than the Inflexible, and, as her turrets are finished and armed, the visitors had an opportunity of seeing how easily heavy guns can be worked by machinery. On the quay alongside the Thunderer 650 lads from the St. Vincent training ship and 300 seamen gunners from the Excellent were drawn up for inspection. The visitors then went on board the Iris, a steel clipper, and the Glatton, a ship of the enlarged monitor class, after which the Speaker and about a score of guests were led off to the residence of Admiral Foley to luncheon, while the remainder of the company was received on board the Thunderer by Lord Charles Beresford and Captain Wilson, his commanding officer. After luncheon the Thunderer was eagerly inspected, and visitors ascended the flying deck and breastwork deck to witness the evolutions of the crew, who, under the orders of Captain Wilson and Lord Charles Beresford, evinced remarkable smartness in clearing the impediments, such as stanchions, catheads, boats, davits, etc., removing the glass illuminators from the deck and substituting armor coverings, and beating to quarters in readiness for an engagement, all being completed in three or four minutes. A Gatling gun was hoisted in the tops, whence it would sweep an enemy's decks. The turrets were revolved and the guns worked, all being done in a manner that elicited the warm encomiums of the visitors. Attention was next directed to the Vesuvius torpedo vessel, Captain Morgan, lying just astern, beside which was a dingy, from which a Whitehead torpedo was dispatched in the direction of a boat some distance out in the basin. Next, a launch, with no one on board, and steered by electricity, left the Vesuvius, and dropped two counter-mines, which were exploded from the Vesuvius. Illustration was also given of the method of clearing channels of torpedoes and other obstructions. On leaving the Thunderer the visitors went in steam launches to the Vernon torpedo school-ship, Captain W. Arthur, where a lecture on torpedo warfare was delivered by Commander Wilson, experiments were made to show the effect of gun-cotton in various states, and a boat was sent from the ship with spar torpedoes, which were fired by electricity.

ring and secured the other rope to the tent-pole. Thus Cognac found himself unable to follow the bent of his inclination any further.

Prof. Tapp then retired from the ring, and in a few moments returned armed, as he expressed it. He had on an overcoat and buckskin gloves. In the inside pockets of the overcoat he had two small electro-galvanic batteries, one on each side. These were connected by an insulated wire that passed behind his back. A wire ran from each battery, one being positive and the other negative, passing down inside of the sleeve to his gloves and connected with a small metallic plate covering the ball of the thumb. He had also a bridle-bit, with long reins attached. The bit was wound with coil of copper wire, which extended along each strap to a small button. With a little difficulty he got the bit in the horse's mouth, the bridle being put over his head piecemeal.

During this process Cognac fought with his mouth and forefeet as best he could, but he did not show any disposition to use his hind feet. The Professor then took the reins, one in each hand; he kept the thumb of his left hand constantly on the button of the strap; his right thumb he held over the other button, but not in contact with it, except when he wanted to give the horse a dose of lightning. When all was ready, he dropped his right thumb on the positive button, giving at first but a light charge. Cognac started as if he had been struck by a bullet. As the shocks were increased in strength the animal plunged and reared as much as his strong fastenings would permit. At length the side rope was loosened, and he had the full circuit of the ring. Tapp let on the electric fluid, and Cognac reared high in the air, endeavoring to plunge at his tormentor, but the Professor kept his eye on him, and by the slightest movement of his thumb created a wall which the horse could not cross.

It was a magnificent sight—the horse, covered with foam, fretting, chafing and panting, reared and attempted to throw himself forward upon the Professor, but the brute strength and ferocity paled before the behest of science, and Cognac was powerless to do harm. The experiments continued about twenty minutes, when the Professor concluded to test the docility of the animal. He said that the principal thing to be overcome was Cognac's disposition to bite. Tapp approached him, stroked him on the body, then on the head, and took hold of his nose. The horse having become convinced that he had found his master, permitted this, and even showed the same docility toward the Professor's assistant.

Prof. Tapp thinks the galvanic treatment is a success, and in this he was concurred with by a number of horsemen in the audience, although others thought differently, as the animal exhibited his usual viciousness toward any others who approached him.

Before Cognac was taken from the ring he would come and go back at his trainer's command, and in many respects act like a good-tempered horse. At last Prof. Tapp hitched Cognac up in a buggy, and the gates having been thrown open, he drove several blocks and returned. There were a great many people watching to see how the horse would acquit himself in harness; he behaved just like any other horse, and but for the fact that the "man-eater" was followed by a large crowd, no one would have suspected that he was the distinguished animal that so much had been heard about.

W. Elliott, of Chowbent, near Manchester, and of which Mr. Macdermott, of London, the patentee of the coal perforator, is the agent. It is a most effective instrument, and is known as the "Parallel Multiple Wedge Expander," and not only brings the coal down after it has been holed, but without the latter process, by forcing it toward a loose end. The wedge is made of the best quality of steel, while its power of expansion is almost unlimited, and as the work can be carried on without any break whatever, it brings the coal down in less time than is required in blasting. A short time since some interesting experiments were made with the wedge at the extensive collieries of Messrs. Wood & Son, Scot Lane, Blackrod, and West Houghton, in the Wigan district, in the presence of a considerable number of practical men, who were much struck with the simplicity of the invention, its lightness, and moderate cost. Mr. Elliott, the patentee, conducted the experiments, along with whom was Mr. John Unsworth, the manager of Messrs. Wood & Son's pits. The first trial was made in what is known as the "Yard Mine," a seam of coal about 30 ins. in thickness, worked on the longwall principle. The place selected was where the roof was of a rough scaly nature, so that even powder could scarcely operate successfully on it. The coal was first holed or undercut to a depth of 3 ft. 6 ins. and 8 yards in length, and then a hole for the insertion of the wedge was drilled by Macdermott's patent "rock perforator" in a very short time near to the roof. The point of the wedge was then inserted in the hole, and two other parts were also put in and driven home alternately by a sledge hammer. The result was more than any of those present anticipated, for the coal came down very clean, and in a very large quantity, in marketable condition. A second wedge was at hand as a reserve in the event of the first one turning out to be unequal to the work required, but which it was stated was very seldom the case. The next trial was on the roof of the same pit, which is generally brought down with some difficulty. But here the wedge did what was required of it most effectually, for it brought down a vast quantity of stuff in a comparatively short time, much greater, indeed, than could have been obtained by blasting in the ordinary way. The apparatus was then taken to the well-known Arley seam, where operations were commenced in the "wide-work," the bed of coal being ... The seam was holed ... yards in length ...

ELLIOTT

and fully bore out all that the patentee had said could be effected by his invention. A few days afterward a third trial was made in the Arley seam at another pit belonging to the Messrs. Wood, where the coal was worked on the "pillar and stall" system. The wedge was put in operation in a pair of "down brows," and driven on the face of the coal. These places were 12 ft. wide, and the coal having been holed and cut on one side the wedge was put in on the opposite side of the "cutting," about 1 ft. from the roof and about the same distance from the side. The effect was ...

Taming Malicious Horses by Electricity.

There is now in California a mottled gray thoroughbred stallion called Cognac, born in Normandy, France, of a most symmetrical and powerful mold. At his native home he was docile, and was worked at the plow. He was imported to the United States two years ago, being then five years old, and became the property of a man in Illinois. One day his owner put a halter on him, the style of which he took as a mortal affront, and he became refractory. All attempts to subdue him were in vain. He was so terribly beaten about the head that for some weeks he was but little better than a dead horse. He recovered, and has ever since exhibited a deadly hostility toward man, and was therefore called the "man-eating horse," though perfectly harmless to animals of his own species.

The way of taming horses by electricity, of which we have before spoken, is now practiced in San Francisco by Prof. Tapp, and this gentleman undertook to tame Cognac in this way, and did it at a public exhibition of his method. Some two or three hundred spectators assembled to see how the animal would conduct himself under the electrifying effects of a galvanic battery. The novelty of the experiment and the fame of this tamer and of the horse attracted the spectators. The ring inclosure was about seven feet high, and the seats for spectators were elevated still over this, so that they were presumably out of the reach of Cognac. Notwithstanding this, he came very near making ... citizen who was unwarily leaning over the temporary rail that surmounted the ring inclosure.

The horse was running at his freedom in the ring, and charged with a wild fury at every person who approached the railing, although they were above his head. He seized the gentleman in question by the coat lappel, taking also his vest, shirt, and undershirt in his teeth, and, being an immensely powerful animal, it was with the greatest difficulty that the man was kept from being dragged into the ring and killed. As

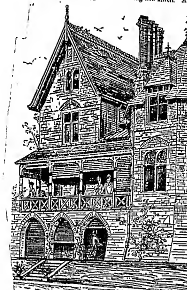

Fig. 1.—Application of the Self-Coiling Venetian Shutters.

it was, the horse got away with a large piece of broadcloth coat and a hearty mouthful of vest, shirt, and red flannel under-garment, and the man's breast was discolored as if he had received a very heavy blow. This was before the audience had assembled or the horse-tamer had come in.

At two o'clock the work of securing Cognac began, and by a little maneuvring two ropes were made fast

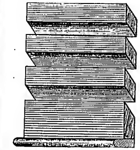

Fig. 2.—Section of Blind.

to the headstall he wore. This was accomplished by the Professor and an assistant, who stood on the outside of the entrance door, which was opened sufficiently to admit a man's arm; Cognac keeping his nose thrust close to the opening in the apparent hope of getting a gulp at somebody. One of the ropes was then passed along the corridor in front of the seats and made fast to an upright post. Then the trainer entered the ring and secured the other rope to the tent-pole. Thus Cognac found himself unable to follow the bent of his inclination any further.

Prof. Tapp then retired from the ring, and in a few moments returned armed, as he expressed it. He had on an overcoat and buckskin gloves. In the inside pockets of the overcoat he had two small electro-galvanic batteries, one on each side. These were connected by an insulated wire that passed behind his back. A wire ran from each battery, one being positive and the other negative, passing down inside of the sleeve to his gloves and connected with a small metallic plate covering the ball of the thumb. He had also a bridle-bit, with long reins attached. The bit was wound with coil of copper wire, which extended along each strap to a small button. With a little difficulty he got the bit in the horse's mouth, the bridle being put over his head piecemeal.

During this process Cognac fought with his mouth and forefeet as best he could, but he did not show any disposition to use his hind feet. The Professor then took the reins, one in each hand; he kept the thumb of his left hand constantly on the button of the strap; his right thumb he held over the other button, but not in contact with it, except when he wanted to give the horse a dose of lightning. When all was ready, he dropped his right thumb on the positive button, giving at first but a light charge. Cognac started as if he had been struck by a bullet. As the shocks were increased in strength the animal plunged and roared as much as his strong fastenings would permit. At length the side rope was loosened, and he had the full circuit of the ring. Tapp let on the electric fluid, and Cognac reared high in the air, endeavoring to plunge at his tormentor, but the Professor kept his eye on him, and by the slightest movement of his thumb created a wall which the horse could not cross.

It was a magnificent sight—the horse, covered with foam, fretting, chafing and panting, reared and attempted to throw himself forward upon the Professor, but the brute strength and fierceness paled before the behest of science, and Cognac was powerless to do harm. The experiments continued about twenty minutes, when the Professor concluded to test the docility of the animal. He said that the principal thing to be overcome was Cognac's disposition to bite. Tapp approached him, stroked him on the body, then on the head, and took hold of his nose. The horse having become convinced that he had found his master, permitted this, and even showed the same docility toward the Professor's assistant.

Prof. Tapp thinks the galvanic treatment is a success, and in this he was concurred with by a number of horsemen in the audience, although others thought differently, as the animal exhibited his usual viciousness toward any others who approached him.

Before Cognac was taken from the ring he would come and go back at his trainer's command, and in many respects act like a good-tempered horse. At last Prof. Tapp hitched Cognac up to a buggy, and the gates having been thrown open, he drove several blocks and returned. There were a great many people watching to see how the horse would acquit himself in harness; he behaved just like any other horse, and but for the fact that the "man-eater" was followed by a large crowd, no one would have suspected that he was the distinguished animal that so much had been heard about.

Photo-Electricity of Fluorspar. 26/2/78

M. Hankel, at the Saxon Academy of Sciences, recently described the results of some experiments he had made on the electric action of light on crystals of fluorspar. After exposure to sunlight, the center of a face of the crystal is found to have a marked negative potential, while the potential of the sides of the face is much less strong and sometimes positive. On sifting the sunlight through colored glasses, a layer of water, or a solution of alum or sulphate of quinine, it was found that the chemical rays are the most active. A too strong concentration of light on the face of the crystal destroyed its sensibility to the further action of light. An exposure of the crystal to a temperature of 95° produced the lowest positive potentials at all points of the crystal while it was cooling.

[31061.]—Electricity and Rheumatism.—To "Sigma."—I was not treated by electricity. In some cases I should say that electricity might be usefully employed, though my faith in its action in rheumatism is limited. I may say I have not been treated at all, but have been my own doctor, except during the acute stage, in which, of course, I could do nothing, and required medical attendance to keep watch against the disease attacking the heart. For some months I endured much pain because, besides every joint in the body being affected, the stomach was constantly attacked, and there was constant pain round about the heart apparently, but really, no doubt, in the muscles among the ribs. Happily, I have got rid of all these, and the pains in the joints seem to slowly diminish, and so give some hope of driving the enemy out in time. The treatment I have adopted is, in essence, that sketched in my letters referred to, using little medicine except when its use was indicated, and that little being—podophyllin, when the liver seemed sluggish; carbonate of potash more frequently, with small doses of iodide of potassium when pains sharpened, and bromide when they took the form of persistent headache. Local pains I met with wet bandages and flannel wrappings, followed by douches of gradually colder water and rubbing with good Turkish towels. The main point, however, is careful management of the general health; as much exercise as possible within the limit of fatigue; as much open air as possible when the weather is fine; nutritious diet of the simplest character; daily washing and rubbing of the whole body, with frequent Turkish baths of a simple character, such as one can manage at home easily enough. In fact, every care should be taken to give the internal organs fair play, and to get the skin into wholesome active condition; avoiding chills carefully, and wearing flannel by day, and sleeping on, or rather in, a blanket by night. This latter I believe to be most important, and to do much towards checking or preventing the sciatica, which usually accompanies rheumatism. The most effective way I have found of applying all these has been at the seaside in warm weather, selecting a bracing tonic location, and bathing regularly, not in the cold damp boxes provided for the purpose, but at some open part where, after a few minutes in the water, and the following rub down, I could lie peacefully on the warm sand, and let the sun and air do their work in bringing the skin back to a more natural condition than our civilised clothing gets it into. This of course implies either a companion or a perfect familiarity with the water; the latter is almost essential for such a case; and, for my own part, till the weakness and pain of rheumatism warned me that I must not trust to my own powers, I was as much at ease in the sea as on the land, and have, in fact, gone to sleep floating on a warm calm day. Possibly this may make sea bathing more useful to me than to others, who would not have the same sense of enjoyment in it.—Sigma.

[32147.]—Electrical Indicator. 25 I think, with J. Jones, that electrical means are too complicated for "An Old Reader's" purpose. He says he wants it done by electricity, because laying the mile of pipe is out of the question. But if he will follow me I will try and show that the sounding apparatus which he mentions, and calls the "patent sounder," will act perfectly over a mile, or over two miles if necessary. The "patent sounder" is for the purpose of showing exactly how much a body of water is rising or falling—thus, water rising or falling in a cistern, or in a ship's hold, or in a tidal river—such as our friend wants to measure—and its action is simply this. If it is wanted to know how much water there is in a ship's hold, a metal box, about 6in. square, is secured to the bottom of the hold, and a hole having been made in the bottom of the box, so that the water can get into it, this part of the apparatus is ready; the box is, of course, full of air. And should the ship spring a leak, or, through any other cause, should water get into the hold, the water as it increased in depth, would enter through the hole into the box and compress the air in it, and the higher the water rose in the hold the more the air would be compressed. What the "patent sounder" does is to show on an indicator the amount of this compression, and this is done by having a small pipe from the box to the indicator, which is so marked that you see clearly what depth the water is in the hold. Now, if I understand "An Old Reader's" query, he wants nothing more than a "patent sounder," (which he appears to understand), rigged up with a mile of pipe from the box at the river to the indicator at the office. The pipe will have to be the smallest he can procure, and the box at the river as large as possible. Thus, if he uses the pipe that is sold for pneumatic bells, which is ⅛in. inside diameter, or ⅛in. iron pipe, the box would have to be at least 12in. square. The best size, I believe, would be about 24 × 24 × 6in. deep, the object being always to have much more air space in the box than in the whole of the pipe. If he goes in for this plan, and wants economy, buy the pipe from the maker, and not from dealer, and a mile of this size won't amount to much money. There are two or three makers of the pneumatic tube in London. The indicator will have to be bought from the patentees. I have read "Draughtsman's" letter, and think his plan very ingenious, and will look out to see what our electrical friends say about it.—Pneumatic.

MOTEURS ET GÉNÉRATEURS

DE L'EMPLOI DE L'ÉLECTRICITÉ ET DE L'INFLUENCE DU ZINC DANS LES CHAUDIÈRES A VAPEUR POUR EMPÊCHER LES INCRUSTATIONS

Par M. Ferd. Fischer, à Hanovre.

Déjà, en 1840, on avait cru observer des manifestations d'électricité dans les chaudières à vapeur. Armstrong, Faraday, Pattison, Schafhaütl s'occupèrent de cette question. Les uns pensaient que l'évaporation produisait de grandes quantités d'électricité, d'autres attribuaient cette production à la chaleur devenant libre lorsque la vapeur se détend; d'autres enfin admettaient que l'électricité joue un rôle dans les explosions de chaudières.

Faraday montra que l'électricité est produite seulement lorsque la vapeur est chargée d'eau et par le frottement contre les parois.

Armstrong, Schäfer, Parry, Ramsbottom et quelques autres ingénieurs croyaient qu'il existait une relation entre le développement de l'électricité et la formation des incrustations, un certain nombre d'expériences furent faites à ce point de vue.

On pensait déjà en 1826 que le zinc, en contact avec le fer, empêchait, tant qu'il restait à l'état métallique, l'oxydation du fer. M. Fischer partageait cette opinion, ses expériences ont démontré que l'action du zinc était insignifiante.

M. Fischer n'a pas pu constater le plus faible courant électrique. Il décrit ses expériences de la manière suivante :

La question « le zinc a-t-il de l'influence sur la formation des incrustations dans les chaudières, et, s'il en a, quelle est la nature de son action? » ne peut être résolue que par l'expérience. Un industriel, M. Knovenagel, président de l'Association pour la surveillance des chaudières du Hanovre, a bien voulu me permettre d'installer une petite chaudière simple pour faire cette étude. Un morceau de tube de chaudière était fermé à une extrémité par une plaque qui portait la soupape de sûreté; le fond opposé portait le manomètre et un tube de verre, ce fond était fixé avec des boulons, le tout reposait sur un bâti en fer.

A travers le tube de verre, on introduisit un gros fil de fer dont une extrémité plongeait dans l'eau de la chaudière, et dont l'autre extrémité pouvait être mise en communication avec différents points de l'extérieur de la chaudière, que l'on remplissait d'eau jusqu'aux deux tiers environ et que l'on chauffait avec du gaz jusqu'à 2 kilogr. de pression, de manière à faire fortement souffler la soupape de sûreté.

La chaudière étant remplie soit d'eau distillée, soit de différentes dissolutions, je n'ai pu constater, avec un galvanomètre très-sensible, la moindre trace d'électricité.

On fixa alors, à l'extrémité du fil de fer qui plongeait dans la chaudière, un lingot de zinc pesant 90 grammes; ce lingot était placé de telle manière qu'il était en contact sur toute sa longueur avec le flanc de la chaudière. On remplissait alors la chaudière avec une dissolution saturée de gypse cristallisé, et on chauffa à la pression de 2 kilogr. L'extrémité extérieure du fil de fer était reliée à un fil de cuivre faisant deux fois le tour d'une boussole et dont l'extrémité opposée se reliait également à un fil de fer que l'on mettait à volonté en communication avec un point de l'extérieur de la chaudière. Cette disposition avait pour but d'éviter des courants thermiques possibles. Lorsque le circuit fut fermé, il s'établit bientôt un courant allant de l'extérieur de la chaudière au lingot de zinc, et l'aiguille magnétique fut déviée de 8 degrés. L'intérieur de la chaudière en contact avec le zinc était électrisé négativement, l'extérieur de la chaudière positivement. L'expérience dura quatre jours; chaque jour la chaudière était chauffée de quatre à six heures à 2 kilogr. de pression, l'eau évaporée était remplacée par la solution saturée de gypse. Le courant électrique observé au début diminua rapidement; le soir du quatrième jour on ne pouvait plus le constater qu'au moyen du multiplicateur. L'appareil étant disposé de la même manière, mais sans lingot de zinc, si l'on plaçait dans le circuit une batterie de six éléments Leclanché, la déviation de l'aiguille était de 25 degrés; cette batterie, appliquée à un appareil à décomposer l'eau, donnait en dix minutes 5,4 centimètres cubes d'hydrogène. Comme les courants électriques sont proportionnels aux tangentes des angles de déviation, le courant électrique produit au début aurait donné 1,64 centimètres cubes, soit $\frac{15}{100}$ milligrammes d'hydrogène, ce qui représente à peine 0,015 unités. Ce courant était donc faible même pendant les premières heures de l'expérience. Si l'on desserre les vis de pression qui assurent la communication entre le fil de fer et le fil de cuivre ou si le zinc n'est pas mis en communication avec l'extérieur de la chaudière par un circuit isolé, il y a sans doute encore des tensions électriques, on ne peut toutefois admettre que ces tensions soient les mêmes.

Lorsque l'on eut évaporé de la dissolution de gypse environ sept fois le contenu de la chaudière, on arrêta l'expérience et la chaudière fut ouverte. Le zinc avait perdu son éclat métallique, il était recouvert d'une couche mince de sulfate de chaux et d'oxyde de zinc, et aussi de sulfate de zinc basique ($4ZnO, SO^3$). La plaque de feu de la chaudière était recouverte d'une couche adhérente de sulfate de chaux de 2 millimètres d'épaisseur, le reste de la chaudière, baigné par l'eau, était recouvert d'une très-mince couche de sulfate de chaux. *L'intérieur de la chaudière, principalement dans la partie occupée par la vapeur, était oxydé.*

L'eau de la chaudière avait une réaction basique et ne contenait pas de traces de zinc, la boue qui se trouvait non adhérente dans la chaudière, en très-petite quantité, avait la composition suivante :

DE L'EMPLOI

DE L'ÉLECTRICITÉ ET DE L'INFLUENCE DU ZINC

DANS LES CHAUDIÈRES A VAPEUR POUR EMPÊCHER LES INCRUSTATIONS

Par M. Ferd. Fischer, à Hanovre.

(2e article [1].)

Si l'on fait bouillir dans une capsule de fer ouverte une dissolution de chlorure de calcium avec un lingot de zinc, un actif dégagement de gaz se produit. Pour étudier cette réaction, nous avons fait les expériences suivantes. Dans des fioles à réaction de 100 centimètres cubes de capacité, on plaçait seule une feuille de zinc pur de 13 centimètres de long, pesant 15 grammes et brisée en trois morceaux; dans d'autres fioles on plaçait des feuilles semblables, entourées d'un fil de fer décapé de 24 centimètres de long, pesant 1,8 gramme. Les fioles étaient alors remplies de dissolution bouillante et leur orifice fermé par des bouchons de caoutchouc, percés d'un orifice portant un tube de dégagement permettant de recueillir sur l'eau les gaz dégagés.

Essai nº 1. — Zinc et dissolution à 2 % de chlorure de calcium. Après vingt-quatre heures de repos, aucun changement. Si l'on chauffait pendant deux heures à 100°, quelques bulles de gaz se produisaient. Le zinc perdait son éclat métallique, le liquide se troublait un peu par suite de la production d'un précipité blanc.

Essai nº 2. — Même essai avec une solution à 1 % de chlorure de magnésium, mêmes résultats, quelques flocons de précipité.

Essai nº 3. — Zinc et fil de fer disposés de manière que les métaux ne soient pas en contact immédiat, dissolution de chlorure de magnésium. Après vingt-quatre heures de repos, quelques bulles de gaz s'étaient produites, le dépôt boueux qui s'était formé sur le zinc était coloré en jaune par l'oxyde de fer. Si l'on maintenait pendant deux heures la température entre 95 et 100 degrés, quelques bulles de gaz se produisaient au début, mais aussi bien sur le zinc que sur le fer. Les deux métaux perdaient rapidement leur éclat métallique, ce qui rendait impossible à apprécier toute action ultérieure. Le précipité qui se formait était assez coloré et se déposait en poussière. La solution était neutre et ne contenait pas de zinc.

Essai nº 4. — Même essai, les plaques de zinc entourées par le fil de fer bien serré. Au bout de vingt-quatre heures, 0,8 centimètre cube d'hydrogène s'était dégagé, le zinc était noyé dans un précipité volumineux que traversaient quelques bulles de gaz. On chauffait pendant deux heures entre 95 et 100°, et 12 centimètres cubes d'hydrogène se dégageaient. Le zinc perdait son éclat métallique, le fer devenait d'un noir gris et était presque complètement enveloppé d'une petite croûte blanche mince. Sur le zinc, aucun dépôt n'apparaissait. Le dégagement d'hydrogène diminuait rapidement, mais n'avait pas encore cessé au bout de vingt-quatre heures. La solution présentait une faible réaction alcaline et contenait des traces de zinc.

Essai nº 5. — Les plaques de zinc entourées par le fil de fer, solution de chlorure de calcium. Au bout de vingt-quatre heures, 1 centimètre cube d'hydrogène s'était dégagé. Le zinc était noyé dans un dépôt volumineux que traversaient quelques bulles de gaz. En chauffant entre 95 et 100°, on obtenait en deux heures et demie 24 centimètres cubes d'hydrogène. Le dégagement diminuait rapidement et était inappréciable à la fin de l'expérience. Zinc et fer perdaient leur éclat métallique; il se formait un précipité pulvérulent; la dissolution avait une réaction alcaline et ne contenait pas de zinc.

Essai nº 6. — Même expérience avec une dissolution saturée de gypse. Au bout de vingt-quatre heures, pas de changement. En deux heures de chauffage à 100°, on obtint 4,8 centimètres cubes d'hydrogène. Le zinc avait perdu son éclat métallique; le fer était en partie devenu gris noir. La dissolution était neutre et ne contenait pas de zinc.

Essai nº 7. — Même essai avec une solution à 5 % de sulfate de magnésie ($Mg. SO^3 7HO$). Au bout de vingt-quatre heures, quelques bulles de gaz seulement s'étaient produites; ces bulles adhéraient quelques-unes au zinc, mais la plupart au fer; un précipité assez volumineux se manifestait. Si l'on chauffait pendant deux heures de 95 à 100°, on constatait le dégagement de 5,8 centimètres cubes d'hydrogène. Dans ce cas encore, le dégagement de gaz diminuait jusqu'à devenir nul, bien que le zinc eût conservé sur une partie de sa surface l'aspect métallique. Le fer était recouvert entièrement d'un dépôt blanc. Ce dépôt ne se remarquait pas sur le zinc. La dissolution présentait une très-faible réaction alcaline et contenait un peu de zinc dissous.

1. Voir *Ann. Ind.* du 17 mars 1878, col. 319.

57

Essai nº 8. — Même expérience avec de l'eau distillée. Au bout de vingt-quatre heures, quelques bulles de gaz s'étaient montrées. Le zinc était enveloppé d'une couche mince d'un précipité jaunâtre de faible densité. Deux heures de chauffage à 100° donnaient 3,8 centimètres cubes d'hydrogène; un précipité ferrugineux et pulvérulent se déposait. Le zinc et le fer perdaient leur aspect métallique et le dégagement d'hydrogène cessait. L'eau ne contenait pas de zinc dissous.

Essai nº 9. — Pour étudier plus complètement l'action du fer sur la production de l'hydrogène, on se servit d'une lame de zinc de 6 centimètres de long enveloppée sur une longueur de 1 centimètre de fil de fer décapé, et on la plaça sous une cloche de verre graduée, dans une dissolution à 5 % de chlorure de calcium. Il se produisit sur le fer un dégagement d'hydrogène passablement actif, quelques bulles de gaz se formèrent aussi sur toute la longueur de la feuille de zinc. Après deux jours d'expérience, le dégagement du gaz cessait. Le zinc était devenu gris, le fer était resté complètement décapé. Il s'était formé un précipité assez abondant et volumineux, composé d'hydrate d'oxyde de zinc, d'oxychlorure de zinc et d'un peu de carbonate de chaux, la solution présentait une réaction alcaline.

Ces expériences démontrent suffisamment la solidité de l'hypothèse de Seiller, que des courants électriques passent constamment entre le zinc et le fer et décomposent les dissolutions salines, de sorte que par exemple dans l'eau gypseuse le calcium se précipite sur le fer et le radical acide SO^4 sur le zinc. En conséquence, chaque molécule de calcium décomposera immédiatement deux molécules d'eau en formant de l'hydrate de chaux et dégageant de l'hydrogène.

L'acide sulfurique se combinera au zinc et donnera du sulfate de zinc (Zn,SO_4). Ces deux composés en présence l'un de l'autre se transformeront instantanément en sulfate de chaux et en hydrate d'oxyde de zinc. Le gypse se trouve donc reconstitué; une partie se déposera sous forme de croûtes, et une très-faible partie seulement se déposera en boue avec l'hydrate d'oxyde de zinc. De même, suivant Gunmaille, avec des eaux contenant du sulfate de magnésie, il se reformera du sulfate de magnésie accompagné d'un précipité pulvérulent. Quand on aura affaire à des chlorures ou à des carbonates, des transformations analogues auront lieu; on ne voit donc pas bien comment la formation des incrustations pourrait être empêchée. Dans les expériences que nous avons citées, le zinc, bien qu'il soit oxydé, a cependant conservé sa forme primitive, il ne peut donc exister en dissolution dans l'eau ou précipité dans les boues qu'en très-faible quantité. En outre, dans l'électrolyse d'un mélange de dissolutions salines par un courant aussi faible que celui qui se développe dans les circonstances dans lesquelles nous nous trouvons, il n'y a jamais qu'un sel décomposé, et cette décomposition a lieu dans l'ordre suivant lequel les métaux se précipitent les uns les autres. Ainsi le zinc d'abord, le magnésium et le calcium ensuite, devraient se précipiter avant les combinaisons alcalines. Il n'y a donc pas lieu, dans le cas qui nous occupe, de prévoir une décomposition des sels de chaux et de magnésie.

Dans les expériences que nous avons citées, 15 grammes de zinc en contact avec le fer à la température ordinaire ne donnent, dans une solution de chlorure de magnésium ou de chlorure de calcium, pas même 1 milligramme d'hydrogène; à 100° pendant deux heures pas plus de 2 milligrammes; dans les sulfates de magnésie ou de chaux à peine 0,5 milligramme; dans l'eau distillée 0,3 milligramme d'hydrogène. Le zinc est transformé en oxychlorure insoluble, en sulfate basique et en hydrate d'oxyde de zinc qui enveloppent le métal; une partie des sels de chaux et de magnésie est également transformée en combinaisons basiques, ou séparée à l'état d'hydrates. Le contact des métaux se trouve ainsi interrompu. De plus, l'hydrogène formé empêche le passage du courant. La polarisation diminue aussi beaucoup quand la température s'élève, d'autres actions diminuent également la tension électrique. Toutes ces raisons expliquent suffisamment la rapide diminution du courant.

Dans les chaudières à vapeur, bien qu'elles ne présentent jamais une surface métallique propre, il se produit aussi au début un léger dégagement de gaz; on peut admettre que ce dégagement et la production simultanée de précipités insolubles troublent la formation des incrustations, surtout si l'on admet l'exactitude de l'hypothèse de Scheibler [1]. Mais au bout de peu de temps, cette formation d'hydrogène à la surface du fer cesse, et le zinc est de plus en plus rongé par l'action des dissolutions salines et de l'oxygène contenu dans l'eau d'alimentation, s'il n'est pas protégé contre cette attaque par les dépôts eux-mêmes.

Nous en concluons que « *le zinc ne peut prévenir les incrustations que dans des cas très-particuliers, et que c'est à peine s'il mérite d'être préféré aux agents qui opèrent mécaniquement.* »

Fichl et d'autres ingénieurs avec lui proposent de placer la chaudière sur le passage d'un courant produit par une pile extérieure. Ce procédé ne paraît guère pratique; en effet, d'après les règles de Faraday sur l'action électrolithique, si les éléments de la pile sont placés de manière que le courant les traverse tous, chacun de ces éléments consommera, pour un équivalent d'une combinaison décomposée, un équivalent de zinc, d'acide sulfurique, d'acide nitrique, etc. Si nous négligeons les pertes notables dues à la résistance du circuit, nous voyons qu'en employant quatre éléments de Bunsen, par exemple, il faudra, pour produire 1 kilogramme d'hydrogène dans la

1. Scheibler pense que ce ne sont pas les parties métalliques polies, mais bien les parois rouillées et rugueuses des chaudières qui permettent la cristallisation et l'adhérence des incrustations. Cette supposition n'est pas confirmée par la pratique; on sait que l'on trouve des incrustations sur les parties les plus polies et les moins oxydées, comme les tubes de laiton, les plaques d'acier, les robinets, les sièges de soupapes, etc.

58

58 **Iron Chip Removed from the Eye by a Magnet.**

At a recent meeting of the Clinical Society of London, Mr. McHardy read notes of a case of removal of a chip of iron from the crystalline lens by means of a powerful magnet. The patient, thirty-one years of age, when at work, was struck in the eye by a fragment of steel from the hammer he was using. When seen, twenty-four hours after, there was evidence of commencing iritis; there was nothing in the vitreous; the eye was less painful than on the night of the accident; its tension normal. Atropine drops were prescribed. The next day there was no pain, and less congestion of the eye; the pupil was well dilated, and allowed of detection of a sharply defined opacity on the interior surface of the lens in a downward-inward direction from the center, the peripheral end being nearer to the margin of the dilated pupil. The cornea was almost normal. The atropine was continued, and absolute rest enjoined. The removal of the chip appeared to be imperative lest it should gravitate downward; at the same time Mr. McHardy was unwilling to remove the lens, and he also thought if it were injured by the forceps it would not be easy to tell if any subsequent opacity of the lens were due to the original injury or to the operation. He therefore had a magnetic spatula constructed by Messrs. Weiss, intending to use it in connection with an electro-magnet. On Mr. B. Carter's suggestion the procedure was modified by employing a powerful bar magnet connected with two Grove's cells. Gradually approaching it to the front of the cornea, when it was four inches away, the chip sprang from the lens to the inner surface of the cornea, and fell into the anterior chamber, whence it was removed, together with a small portion of iris. A patch of opacity exactly corresponding in size to the chip was left on the lens. Subsequently a cataract formed, and the injured lens became absorbed. The patient's vision, aided by a lens of twelve dioptrics, is normal for distant objects. Mr. McHardy acknowledged his indebtedness to Mr. Ladd and Dr. Tibbits for assistance and suggestions, and he referred to a paper by Dr. McKeown, in the *Dublin Journal of Medical Science* for September, 1876, where three or four cases are recorded of the use of magnets in the removal of fragments of steel in the eye.

Mr. Brudenell Carter, having seen the case, stated that the position of the fragment was such that any other attempt at its removal would have jeopardized the eye. If nothing had been done, the fragment would probably have fallen below the iris, and would have set up destructive inflammation; and any attempt at its removal by forceps would certainly have injured the lens. By withdrawing it from its bed and bringing it to the front of the iris, the magnet had obviated these difficulties.

Electric Bell for Incubators. 4/3/79 J. J. W. and others ask if an electric bell arrangement can be employed to indicate when the temperature in an incubator or other heated apartment rises too high, and whether such an apparatus is now in market. *Ans.* We are not aware that such an apparatus is in market, but it would be easy to make one. All that would be necessary would be to make an adjustable insulated metallic rod a part of the circuit, and set it at such a distance from a metallic point also in the circuit that, when the maximum temperature desired is reached, the closing of the circuit would be effected by the expansion of the rod, and to place an ordinary bell-ringing arrangement also in the circuit. The bell would, of course, ring whenever the circuit was closed. A mercury column, in a glass tube, forming a part of the circuit, would be a good substitute for the expanding rod.

78 THE ELECTRIC FUSE AND HEAVY CANNON.—It seems as if we were about to abandon the old method of firing guns on board ship with the lanyard, and to use the electric fuse instead, at any rate, so far as heavy cannon are concerned. For some years past experiments have been carried on in the navy with electric firing, but it is only since we have had to do with very heavy guns, and particularly those in turrets, that this method of discharge has become almost indispensable. To be cooped inside a close iron turret in company with a pair of terrible weapons of 35 or 38 tons, and to experience the full measure of their thunder, is scarcely to be contemplated with indifference; yet this is not the reason, or at least not the principal reason, why the electric current is to be employed in future instead of the gunner's arm. The real cause is twofold; in the first place it is possible to take better aim by using electricity to do the work; and, secondly, the effect of the shots is more terrible. The simultaneous discharge of three or four projectiles against heavy armour has been found capable of penetrating the latter, when single shots are quite unable to do so. A vibration is set up in the iron plating, it is presumed, and in this condition the armour is more vulnerable. Simultaneous firing is impossible by hand and word of command, in the same way as gunners used to fire broadsides in the old three-decker days. To the ear the thunder of discharge might not appear otherwise instantaneous, but the effect upon an ironclad is vastly different if a volley is fired by lanyards, or by a flash of electricity. The other reason is more important still. The guns are so close to the water, and the portholes so limited in size, that sighting along the weapons is frequently a matter of difficulty. The operation is much more easily performed by an officer stationed above, either in the rigging, or in the armoured tower, with which most of our modern ironclads are fitted. Provided with suitable sights and electric wires which lead down into the batteries, the captain, or other officer of the ship, here has the whole of its armament under his hand. He directs at what angle the guns shall be laid, and, watching his opportunity, discharges them simultaneously at the instant he thinks most fit. Situated above the deck he is removed from the bustle and smoke below, and can act with more coolness and judgment, while obviously no time is lost when the critical moment for firing arrives.—*Standard.*

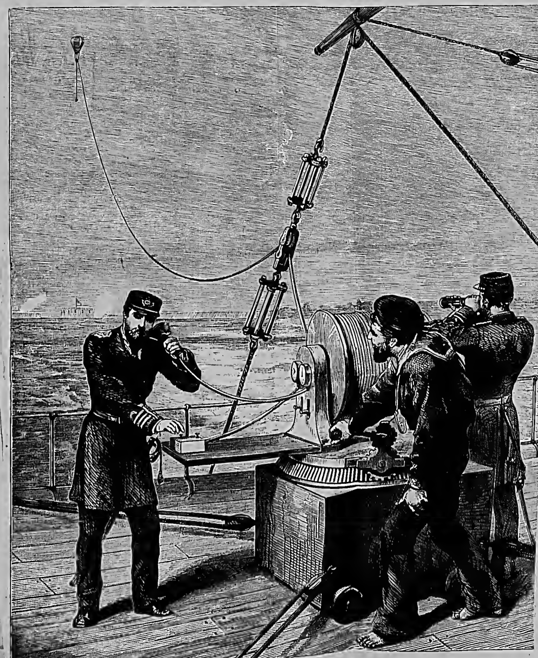
SCIENTIFIC AMERICAN

A WEEKLY JOURNAL OF PRACTICAL INFORMATION, ART, SCIENCE, MECHANICS, CHEMISTRY, AND MANUFACTURES.

Vol. XXXVIII, No. 19. [NEW SERIES.] NEW YORK, MAY 11, 1878. [$3.20 per Annum. [POSTAGE PREPAID.]

AERIAL WARFARE.

The idea first published in these columns of dropping torpedoes into an enemy's camp or cities from balloons seems in a fair way to be put in practical shape abroad. The London *Graphic* publishes the large engraving given herewith, showing how a balloon carrying a large torpedo could be sent over a hostile fort from on shipboard. Our contemporary proposes that gunboats shall be provided with balloons large enough to carry one man and the can of nitro-glycerin or other powerful explosive suspended at considerable distance below the car. To the latter is attached a rope or wire, which is rove through a fair-leader and taken to the winch shown on the poop of vessel. The length of wire paid out as the balloon moves over the point to be attacked is indicated by dials on the side of the winch drum, and by means of a telephone the officer directing operations communicates with the occupant of the car, and receives from him directions when to slacken or reel in the wire. The



THE BALLOON TORPEDO.

creuse également en verre. Cette boule, plus légère que le volume d'eau qu'elle déplace, assure la flottaison des figurines. Mais à la partie inférieure de celles-ci se trouve caché un petit fragment de fer et, dans le socle supportant tout l'appareil, un électro-aimant. L'effet produit se comprend aisément. Quand le courant électrique, provenant d'une pile, anime l'électro-aimant, celui-ci attire de haut en bas le morceau de fer caché dans les figurines : celles-ci descendent au fond du vase. Elles remontent, au contraire, dès que le courant électrique cessant de l'animer, l'électro-aimant redevient inerte et n'exerce plus aucune action sur le fer des figurines.

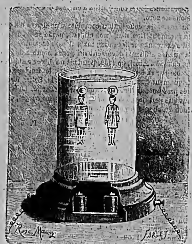


Fig. 1. — Le ludion électrique.

LES POISSONS ÉLECTRIQUES

Les poissons électriques présentent une disposition aussi simple que le ludion décrit plus haut et produisent également un effet très-curieux : ils flottent doucement, ou bien tournent à droite ou se dirigent à gauche au commandement de l'opérateur.

Pour réaliser cet effet, M. de Combettes a placé des poissons en fer peint dans un vase cylindrique en verre monté sur un socle, à l'intérieur duquel est un petit moteur ou tourniquet électrique. Quand on fait passer dans l'électro-aimant de ce moteur le courant d'une pile électrique, l'armature de cet électro-aimant tourne autour de son axe, et, comme elle participe à l'aimantation des bobines de fer, elle entraîne les poissons dans son mouvement de rotation. Si on change le courant de manière à modifier le mouvement du mécanisme électrique, les poissons hésitent un instant puis se remettent à tourner dans un sens opposé à celui de leur précédent mouvement.

Il va sans dire que pour le ludion comme pour les poissons, l'opérateur n'a nul besoin de toucher aux appareils; il doit même, pour ajouter à l'illusion, s'en tenir éloigné. C'est à l'aide d'un petit instrument habilement dissimulé dans sa main ou dans sa poche, un commutateur, pour l'appeler par son nom, qu'il établit ou qu'il rompt la communication de la pile électrique avec le ludion ou le moteur électrique des poissons.

AN ELECTRICAL GYROSCOPE.

BY GEO. M. HOPKINS.

The gyroscope, though now a common toy and familiar to every one, is still a puzzle to scientists. It has been properly called the "mechanical paradox," for, while it depends on gravitation for its peculiar action, it appears indifferent to it.

To render the operation of the gyroscope as nearly continuous as possible, so that its movements may be more thoroughly studied, and to combine another influence with those that unite in the gyroscope of the common form to produce the almost miraculous phenomena exhibited by the instrument, I have applied electricity as a motive agent.

The gyroscope illustrated by the engraving has a weighted base piece, from which projects a pointed standard that supports the moving parts of the instrument. The frame, of which the electro-magnets form a part, has an arm in which is fastened an insulated cup, that rests upon the point of the standard. One terminal of the magnet coil is connected with this cup, and the other terminal is connected with the bar that connects the cores of the two magnets.

Upon the top of the magnet bar a current-breaking spring is supported by a hard rubber insulator, and is arranged to touch a small cylinder on the wheel spindle twice during each revolution of the wheel.

The wheel, whose plane of rotation is at right angles with the magnet cores, carries a soft iron armature, which turns very near the face of the magnet, but does not touch it. The armature is arranged in such relation to the contact surface of the current-breaking cylinder that twice during each revolution, as the armature nears the magnet cores, it is attracted, but immediately the armature comes directly opposite the face of the magnet cores, the current is broken, and the acquired momentum is sufficient to carry the wheel forward until the armature is again within the influence of the magnet.

The current-breaking spring is connected with a fine copper wire, that extends backward as far as the pointed standard, and is coiled several times to render it very flexible, and is finally bent downward so as to dip in mercury contained in an annular vulcanite cup placed on the pointed standard near the base piece.

The base piece is provided with two binding posts for receiving the battery wires. One of the binding posts is connected with the pointed standard, and the other communicates by a small wire with the mercury in the vulcanite cup.

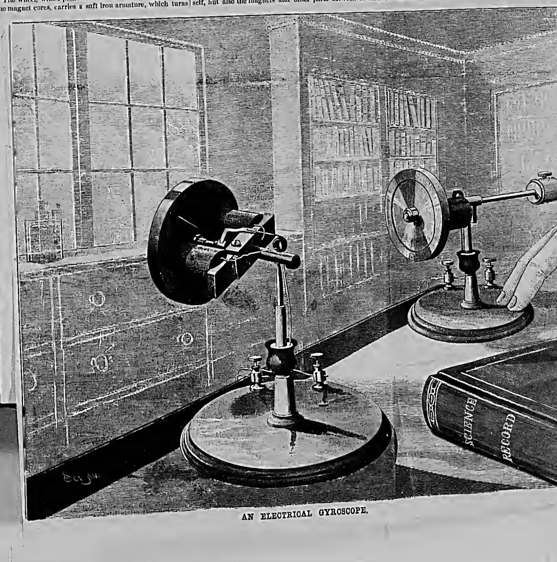
The magnets and wheel, and all of the connected parts, are free to move in any direction on the point of the standard. When two large or four small Bunsen cells are connected with the gyroscope, the wheel revolves with enormous velocity, and upon letting go of the magnets (an operation that requires some dexterity), the wheel sustains not only itself, but also the magnets and other parts between it and the point of the standard, in opposition to gravity. The wheel, besides rotating rapidly on its axis, sets up a slow rotation about the pointed standard in the direction in which the *under side* of the wheel is moving.

By attaching the arm and counter balance shown in the engraving, so as to exactly balance the wheel and magnets on the pointed standard, the whole remains stationary. By *overbalancing* the wheel and magnets, the rotation of the apparatus around the standard is in an opposite direction, or in the direction in which the *top* of the wheel is turning.

This gyroscope illustrates the persistency of a rotating body in maintaining its plane of rotation against the force of gravitation. It also exhibits the result of the combined action of two forces tending to produce rotations about two separate axes lying in the same plane.

The rotation of the wheel upon its axis, produced in this instance by the electro-magnet, and the tendency of the wheel to fall, or rotate in a vertical plane parallel with its axis, result in the rotation of the entire instrument upon a new axis, which is coincident with the pointed standard.

A MODE of equalizing the wear of the cylinders and pistons of horizontal engines, suggested by an English engineer, consists in making the piston-rod with a camber or upward bend, so that, when loaded with the weight of the piston and placed in the cylinder, it assumes a straight line, and transfers the weight to outside guides.



AN ELECTRICAL GYROSCOPE.

Electrician June 78

Another Curious Application of Electricity.—Electricity has been applied to stripping photographic films from glass plates. Photographers know full well that there is scarcely any substance so electric in its nature as a collodion film, and a dry film may be made to adhere firmly to a glass surface if it is simply stroked by the hand to excite it electrically. M. Bolvin believes that the only adhesion of a collodion film to glass, in the ordinary way, is due to its electric state, and it is only when the electric condition is destroyed that the film is repelled so thoroughly that it may be lifted from the plate without difficulty. An excited film certainly adheres very firmly, and can only be peeled off the glass with difficulty, and clings to one's hands and around one's fingers with a disagreeable tenacity. When charged, however, with positive electricity the film comes from the glass immediately, and one has no difficulty in getting it to leave the plate. It is said, that, if we simply cut round the edges with a knife, and then charge the film, first with one kind of electricity and then with another, the collodion image will leave the glass without further trouble. This is certainly a novel application of electricity.

A New Application of Electricity.—Some experiments have been made at Brussels in breaking in horses by means of an electric bridle. The apparatus, called the Engstrom bridle, after its inventor, consists simply in a couple of reins, along which run electric wires. At the end of the reins a small electric battery is attached, which is entirely in the power of the experimenter. By pressing on a little knob the electric current acts on the corners of the horse's mouth, and after a few consecutive or intermittent shocks the animal becomes perfectly docile. A very intractable mare was broken in after one experiment with the bridle. The inventor asserts that runaway horses can immediately be brought to a standstill by means of this apparatus. July 78.

THE ELECTRIC FUSE AND HEAVY CANNON.

Aug 23/78

It seems as if we were about to abandon the old method of firing guns on board ship with the lanyard, and to use the electric fuse instead, at any rate so far as heavy cannon are concerned. For some years past experiments have been carried on in the navy with electric firing, but it is only since we have had to do with very heavy guns, and particularly those in turrets, that this method of discharge has become almost indispensable. To be cooped inside a close iron turret in company with a pair of terrible weapons of 35 or 38 tons, and to experience the full measure of their thunder, is scarcely to be contemplated with indifference; yet this is not the reason, or at least not the principal reason, why the electric current is to be employed in the future instead of the gunner's arm. The real cause is twofold: in the first place it is possible to take better aim by using electricity to do the work; and, secondly, the effect of the shots are more terrible. The simultaneous discharge of three or four projectiles against heavy armor has been found capable of penetrating the latter, when single shots are quite unable to do so. A vibration is set up in the iron plating, it is presumed, and in this condition the armor is more vulnerable. Simultaneous firing is impossible by hand and word of command, in the same way as gunners used to fire broadsides in the old three-decker days. To the ear the thunder of discharge might appear instantaneous, but the effect upon an ironclad is vastly different if a volley is fired by lanyards, or by a flash of electricity. The other reason is more important still. The guns are so close to the water, and the portholes so limited in size, that sighting along the weapons is frequently a matter of difficulty. The operation is much more easily performed by an officer stationed above, either in the rigging or in the armored tower, with which most of our modern ironclads are fitted. Provided with suitable sights and electric wires which lead down into the batteries, the captain, or other officer of the ship, here has the whole of his armament under his hand. He directs at what angle the guns shall be laid, and watching his opportunity, discharges them simultaneously at the instant he thinks most fit. Situated above the deck he is removed from the bustle and smoke below, and can act with more coolness and judgment, while obviously no time is lost when the critical moment for firing arrives.—*London Standard.*

653

ELECTRIC BLASTING.

On Wednesday afternoon a general meeting of the members of the Midland Institute of Mining Engineers was held at the Yorkshire College, Cookridge, Leeds. There was a good attendance. Mr. T. W. Embleton, the ex-president, in the absence of Mr. Carter, of Barnsley, the president, occupied the chair. A most important paper was read by Mr. C. Walker, Manager of Houghton Main Colliery, near Barnsley, "On Blasting in Sinking Pits by Electricity, and an Improved Method of Placing the Shot Holes." The paper, which was well received and criticised, pointed out the advantages of blasting in a 15-feet chamber. By this method he said he had sunk 21 yards through rock in seven days, and during that time only eight hours were lost in making repairs. The writer explained that dynamite, instead of gunpowder was used, and at least a dozen holes were drilled and charged in the shaft at one time. A large number of the holes were bored near the sides of the shaft, and some in the centre, to various depths. The holes having been charged and fuses attached, two pieces of cable composed of indiarubber and roping were attached to two pieces of wire. In the piece—a specimen of which Mr. Walker produced—was a chamber charged with composition. This was first exploded by electricity, and then it ignited a cap, which in turn ignited the dynamite, and in this way a simultaneous explosion was produced. It was also shown that the holes were drilled so far apart as not to impede the work, and whilst one man was pressing the dynamite, another was charging the hole, and a third could fix the fuse. In this way the whole of the holes were ready for firing at nearly the same time. In answer to a question as to what damage was generally done by the firing of so many shots at one time, it was explained that the shots so fired caused but little damage. The action of one seemed to counteract any damage which might arise from the other, by the stones, &c., which were upheaved, beating against each other. In the course of a very able and important discussion, the paper was favourably commented on. Mr. A. Lupton, teacher at the new Mining College, Leeds, referred to his experiences with regard to the cutting of a tunnel where electrical gun shots were used. The system was adopted because a special rule provided that no more than one shot should be fired at one time. Such a rule caused great loss of time in cutting a tunnel, and it was considered that by having a dozen holes connected together and fired simultaneously by an electrical machine, it was practically one shot. No difficulty was found in securing the services of an ordinary workman to use the machine. A cable was used for transmitting the electricity. Other speakers expressed their opinions on the paper, and at the close it was agreed that Mr. Walker should be requested to furnish sections of the strata passed through in the shaft to which his observations referred, as well as the expenditure entailed by that mode of sinking. A paper by Mr. J. E. Dooley, "On Improvements in Safety Lamps," was held over to a future meeting, as was also one to be submitted by Mr. J. W. H. White, "On a Contrivance for Attaching Curves of Endless Ropes on Underground Planes." Aug 17/78

Electricity as a Motive Power.—In the course of a lecture on electricity, delivered by Mr. Gerard Finch, M.A., in connection with the Wigan Mining and Mechanical School, last week, a novel illustration was given of electricity performing mechanical work. A saw-bench was placed on a platform connected with a Siemens dynamo-electric machine, which, in its turn, was connected by wires with the machine outside the hall used for producing the electric light during the lecture. On the electricity being communicated the saw was set in motion, and timber up to 5 inches in thickness was cut into strips. Lord Lindsay, M.P., F.R.S., and President of the Royal Astronomical Society, was in the chair, and among the audience were a large number of the leading colliery proprietors of the district. The latter, our Wigan correspondent states, are inclined to test the practicability of working coal-cutting machines and other underground machinery by electricity. At present compressed air is the only power that can be used for driving these machines without interfering with the ventilation of the workings. Electricity is said to produce equal effect at considerably less cost. It can also be conducted cheaply and easily to any part of the mine by means of wires. 18 Dec

64 916

spots.—*Engineer.*

EDISON'S PHONOMETER.—It is admitted that there is power in the human voice, but hitherto this power has been applied indirectly to produce mechanical results. Mr. Edison in his telephone and phonograph experiments discovered that the vibrations of the vocal cords were capable of producing considerable dynamic effect. Acting on this hint he began experiments on a phonometer, or instrument for measuring the mechanical force of sound waves produced by the human voice. In the course of these experiments he constructed the machine, which exhibits the dynamic force of the voice. The machine has a diaphragm and mouth-piece similar to a phonograph. A spring which is secured to the bed-piece rests on a piece of rubber tubing placed against the diaphragm. This spring carries a pawl that acts on a ratchet or roughened wheel on the fly wheel shaft. A sound made in the mouth-piece creates vibrations in the diaphragm, which are sufficient to propel the fly wheel with considerable velocity. It requires a surprising amount of pressure on the fly wheel shaft to stop the machine, while a continuous sound is made in the mouth-piece. Mr. Edison says he will have no difficulty in making the machine bore a hole through a board; but we consider such an application of the machine of very little utility, as we are familiar with voices that can accomplish the feat without the mechanical appliance.—*Scientific American.*

DANGERS THAT BESET SUBMARINE CABLES.—Every one who has at all studied oceanic telegraphy perfectly understands the dangers to which the shore ends of communicating wires are exposed from the action of currents, the anchors of ships, &c. But the general idea prevailed that once the cable was laid in the gloomy depths of the ocean, it was in safety. Such, however, is not the case, for the inhabitants of those regions seem to resent the intrusion. In many cases, owing to the inequalities of the bottom of the sea, the wires cannot rest wholly on the bed, but in some

than thirty-five feet from the box; its performance suggested to me the multiplication of the carbons on the relay. To the above I may add that when the electrical current used with the carbons is too powerful, a hissing, cracking sound is produced, which is from time to time varied by the introducion of a pure musical note, which often runs through considerable variation in pitch. This voltaic tone may be due to the repulsion exerted by the electrical current on itself, causing one of the carbon points to rise and fall with regularity in a manner analogous to the motion of the Trevelyan rocker, or it may be caused by rapid changes of temperature, and hence in volume of the contact-surfaces. With fourteen small cups it occurred quite frequently." 1878 Aug

PHOTO-ELECTRIC ENGRAVING.

[THE following interesting process is extracted from a paper by Captain J. Waterhouse which appears in the Journal of the Asiatic Society of Bengal:]

Geymet's method of photo-engraving consists in electrotyping from a gelatine relief obtained by the pigment-printing process, and is somewhat similar in principle to Placet's process, but as there are important differences, and the process appears likely to prove of some utility, it may well be treated separately.

According to M. Geymet, who has very fully described the process and all the manipulations of preparing and electrotyping the reliefs in his "*Gravure Héliographique,*" it was the invention of M. Amiro, a French amateur.

Pigmented gelatine tissue is sensitized and exposed to light exactly in the manner heretofore described for the autotype process. It is transferred to a smooth glass or a polished copper plate, developed in warm water, and when dry is metallized and electrotyped. If the subject is one in line or dot only, the above operations are sufficient; but if the subject is a photograph from nature, or any other with gradation of shade, it is necessary to obtain a grain, and this M. Geymet does by taking a copper plate with its surface grained or engraved with a ruled or roulette tint, inking it up in the ordinary way, and then covering it with a coating of transfer collodion. When dry, the film of collodion is stripped off the plate, and carries with it the impression of the grain. This film is then placed between the cliché and the sensitive gelatine film, and serves to break up the shadows in the more transparent parts of the cliché.

A similar process has been used at the Dépôt de la Guerre, in Belgium, for the reproduction of maps.*

Last year, while making some experiments on this process, I succeeded in obtaining the necessary grain by chemical means, which produce a finer and less artificial effect, and I have also made a few other modifications in the process, which may be worth recording at length.

A piece of the ordinary autotype tissue is sensitized in a five per cent. solution of bichromate of potash. When dry, it is exposed to light under a reversed negative, and then transferred in cold water to the surface of a well polished copper plate, and squeegeed down into close contact with it. In order to prevent subsequent adherence to the newly deposited copper in the electrotyping bath, the copper plate is silvered by rubbing it with a little of the following solution mixed with tripoli:

Nitrate of silver	1 part.
Cyanide of potassium	10 parts.
Water	100 "

The gelatine tissue attached to the copper plate is allowed to dry, and then developed in warm water in the usual manner, great care being taken not to loosen the lines, an accident which is very liable to happen, though the preliminary drying of the tissue before development tends to prevent it.

When the image is quite clear from all soluble gelatine, the plate is well drained, and plunged into a bath containing—

Tannin	5 parts.
Strong spirits of wine	100 "

This at once removes all moisture from the gelatine relief, hardens it, and gives it a fine grain, coarser in the shadows than in the lights. The plate remains a few minutes in this bath, till the action is complete in the deepest shadows; the tannin is then washed off with a little spirits of wine, and the plate is allowed to dry.

The gelatine relief has now to be prepared for receiving the electrotype deposit. A band of copper having been soldered to it, the back of the plate is coated with Brunswick black, to prevent deposition of the copper upon it. When the backing is dry, the margins of the picture are cleaned with a little of the silver solution. The gelatine surface then receives a very slight coating of wax dissolved in turpentine, which is well polished off, and is rubbed over with fine plumbago or silver-bronze powder to render the surface conducting. The plate is then ready to be placed in the depositing bath.

Any good electrotyping arrangement may be used, but I prefer a Smee's battery with a separate depositing trough, containing a solution of ten parts each of sulphate of copper and sulphuric acid in one hundred parts of water.

955

A plate of copper, to serve as an anode, and connected with the silver plate of the battery, is laid horizontally about an inch above the bottom of the depositing trough, which should be large enough to allow the plate bearing the gelatine relief to be slipped under the anode. The relief-plate is connected with the zinc plates of the battery, and, when everything else is ready the circuit is completed by slipping it into the depositing trough under the anode. By laying the plates horizontally in this manner the deposit is more even, and the gelatine film seems to be more readily covered with copper.

When the deposit of copper is of sufficient thickness it is separated from the matrix, and only requires a gentle "oil-rubbing" to be fit for printing.

The plates obtained by this method show very good half-tone with an almost imperceptible grain, giving the effect of a fine chalk-drawing.

I have lately tried to obtain the images upon the copper by the double transfer process, making use of a flexible temporary support, consisting of paper coated with India-rubber, as first proposed by Swan, which can easily be removed with benzole after the transfer of the gelatine image to the copper. The grain is given to the image by soaking it in water after the removal of the India-rubber paper, and then applying the solution of tannin in alcohol. This plan seems likely to be successful; if so, it will greatly simplify the operations, and enable engraved plates to be obtained from any ordinary negative without the trouble of reversing.

By electrotyping direct from the gelatine relief, the results are always rather heavier and coarser than they should be, because, although hardened and insoluble, the gelatine relief can always absorb a little of the copper solution in the depositing trough, and consequently the image swells and loses sharpness.

The strong tanning given to the gelatine film and the preliminary coating of wax before metallizing the surface obviate this defect to a considerable extent; but it may perhaps be better to obtain a matrix in lead by pressure from the gelatine relief, and then to obtain the printing plate by electrotyping twice from the lead matrix. This is a more roundabout and expensive method, but it is likely to yield finer results, and has been adopted by Woodbury and Rousselon in their processes.

The process is simple, and, if it could be successfully worked out, it might be usefully employed in this country in reproducing shaded maps and for other miscellaneous purposes. It has the very great advantage over photo-collotype that the plates can be corrected, if necessary, and can be printed in any numbers in the ordinary copper-plate press without risk of breakage or damage to the printing surface.

* See Maes and Hannot, *Traité de Topographie, etc.*, p. 230.

NEW USE OF ELECTRICITY. Feb 24/79

THE French Minister of Public Works (according to the *Moniteur Scientifique*) has been experimenting on the River Lot, in Aveyron, with an electric apparatus designed to reproduce automatically, from a higher to a lower point of the river, the variations of level, so as to give immediate warning of floods, and enable the inhabitants to make what preparation they can. The experiments were made between two points about a mile apart. At the higher, Laroque, is a float which follows the upward and downward motion of the water (without being affected by the current). It communicates its movements, through a battery and conducting wire, to the needle of a graduated scale at Capdenac, the lower point, and the needle thus indicates all the fluctuations of level. At a certain point on the scale is the word danger, and when the needle reaches this, it sets in action a number of bells in the houses on the banks, connected by wire with the instrument. Thus the inhabitants are warned to make ready. This curious apparatus is the invention of M. Gros, of Rodez, and it has met with high approval from the Ministry of Public Works and the General Council of Aveyron. The need of something of the kind has been strongly felt, as floods in that region have proved very disastrous.

One copy one year, postage included ... $3 20
One copy, six months, postage included ... 1 60

Clubs.—One extra copy of THE SCIENTIFIC AMERICAN will be supplied gratis for every club of five subscribers at $3.20 each; additional copies at same proportionate rate. Postage prepaid.

Single copies of any desired number of the SUPPLEMENT sent to one address on receipt of 10 cents.

Remit by postal order. Address

MUNN & CO., 37 Park Row, New York.

The Scientific American Supplement

is a distinct paper from the SCIENTIFIC AMERICAN. THE SUPPLEMENT is issued weekly; every number contains 16 octavo pages, with handsome cover uniform in size with SCIENTIFIC AMERICAN. Terms of subscription for SUPPLEMENT, $5 00 a year, postage paid, to subscribers. Single copies 10 cents. Sold by all news dealers throughout the country.

Combined Rates.—The SCIENTIFIC AMERICAN and SUPPLEMENT will be sent for one year, postage free, on receipt of seven dollars. Both papers to one address or different addresses, as desired.

The safest way to remit is by draft, postal order, or registered letter.

Address MUNN & CO., 37 Park Row, N. Y.

Scientific American Export Edition.

The SCIENTIFIC AMERICAN Export Edition is a large and splendid periodical, issued once a month. Each number contains about one hundred large quarto pages, profusely illustrated, embracing: (1.) Most of the plates and pages of the four preceding weekly issues of the SCIENTIFIC AMERICAN, with its splendid engravings and valuable information; (2.) Commercial, trade, and manufacturing announcements of leading houses. Terms for Export Edition, $5.00 a year, sent prepaid to any part of the world. Single copies 50 cents. Manufacturers and others who desire to secure foreign trade may have large, and handsomely displayed announcements published in this edition at a very moderate cost.

The SCIENTIFIC AMERICAN Export Edition has a large guaranteed circulation in all commercial places throughout the world. Address MUNN & CO., 37 Park Row, New York.

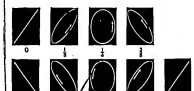
the spring connecting pieces that project from the back of the vibratory tongues.

The holes in the spring connecting pieces are made larger than the needle, and pieces of thin leather are attached to the connecting pieces to form a yielding bearing for the needle. To the outer end of the needle is secured a small concave mirror, in front of which a small plano convex lens is supported by a jointed arm projecting from the main frame of the instrument.

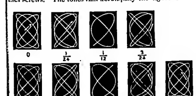


0 $\frac{1}{8}$ $\frac{1}{4}$ $\frac{3}{8}$

$\frac{1}{2}$ $\frac{5}{8}$ $\frac{3}{4}$ $\frac{7}{8}$ 1

FIG. 3.

A beam of parallel rays being thrown on the concave mirror from a lantern or *porte lumière*, and the vibratory tongues being set in operation, a figure will appear upon the screen on which the instrument is focused, which will be the resultant of the two rectangular vibratory motions. This figure depends on the persistence of visual sensations on the retina, for it is really due to the rapid movement of the light spot which is seen when the tongues are at rest. The figure may be varied by moving the slide so that any possible combination of tones within the compass of one and one half octave may be produced. It is interesting to observe the change of figure resulting from the slightest alteration in the adjustment of the slides, or from the change of phase resulting from an alteration in the adjustment of the contact screws. The tones that accompany the figures are full



0 $\frac{1}{24}$ $\frac{1}{12}$ $\frac{3}{24}$

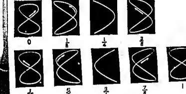
$\frac{1}{6}$ $\frac{5}{24}$ $\frac{1}{4}$ $\frac{7}{24}$ $\frac{1}{3}$

FIG. 5.

and deep, especially if the instrument be mounted on a sounding board. The effect known to musicians by the name of "beat" can be produced by this instrument, so that they may not only be heard with distinctness, but may also be seen.

If only one tongue vibrates a straight line will appear on the screen, which will be inclined at an angle of 45° from the horizontal. The line produced by one of the tongues forms a right angle with the line produced by the other, and when both tongues vibrate simultaneously the two motions combine, and the reflected pencil describes a more or less complex curve, the form of which depends on the number of vibrations of the two tuning forks in a given time.

Fig. 3 shows the luminous image on the screen when the tongues vibrate in unison, and the fractions below each fig-



0 $\frac{1}{8}$ $\frac{1}{4}$ $\frac{3}{8}$

$\frac{1}{2}$ $\frac{5}{8}$ $\frac{3}{4}$ $\frac{7}{8}$ 1

FIG. 4.

ure indicate the difference of phase between them. The curve retains its form when the tongues are in unison, but when they are not quite in unison the initial difference of phase is not preserved, and the curve passes through all its variations. Fig. 4 represents the different appearances of the luminous image when the difference between the vibratory tongues is an octave; and Fig. 5 represents curves when the number of vibrations are as 3 : 4. The loops along the vertical and horizontal edges express the ratio of the combined vibrations. The variety of figures that may be produced by this instrument is endless.

When sunlight is employed to project the figures the mirror may be plain and very small, and the lens may be dispensed with. The figures, when viewed directly in a plain mirror of one inch diameter, appear as wires of burnished gold interwoven in a most complicated and beautiful manner.

[33570.]—Electric Clock.—To "IOSTEPHANOS."—I am very sorry not to have been able to answer your query before, but have been ill. The magnets of my own clocks are about 2in. long, of ⅜in. iron, annealed in charcoal; the poles are very slightly convex, and the armature has a piece of thin oiled silk attached with shellac, to prevent the magnet holding it after the current has ceased flowing. The magnet-arms are covered with paper, and wound with 7 or 8 layers of No. 21 cotton-covered, and the whole soaked in paraffin. I suppose you know the paraffin mentioned is the ordinary solid white paraffin, costing eighteenpence per lb.; paraffin candles should not be used, as they are (or may be) adulterated with stearine, tallow, or some such stuff, which may corrode the copper. It is convenient to join the outer ends of the two coils together, as there is then no danger of the inner ends coming undone, and if they break off close they can be uncoiled a little, while the bungle of twist is avoided, and with it the risk of the tightly-twisted wires touching metallically. I never used reels on any magnet; there is first the trouble of turning them, then they waste valuable space next to the iron, and it is very difficult to secure the iron of the magnet effectively without crushing the reels up. Pegging with wood is, of course, no use; while, on the other hand, the other way takes half an hour to wind, and is entirely satisfactory when done. About half a pound of wire will be more than enough. Your circuit wire is much too thin; 16 or 17 would be better, but of course it is only a question of more battery power. With such a circuit of 24 I should suppose 7 or 8 Léclanché's would be necessary; but I am not so in love with the Léclanchés I used to be. After trying all sorts of variations, I now use pint glass vessels containing 6 per cent. sulphuric acid, and zinc about 12 cm. by 2, half surrounded by platinised silver of twice the width, bent into a third of a circle. Once a month I change the acid, lift the combination (arranged on a strip of wood) out of the old jar into a fresh one, empty, and refill the old and replace with it the next cell. Every other month I replace the zincs, which are fixed in clamp screws faced with platinum, and protected from any of the solution carried up by the escaping gas. Take care that the silver gets no mercury on to it. I should think 6 of these cells would work your fine wire line; but, anyhow, I would use them—the Léclanché's are such a nuisance to recharge, especially the bought ones, and so dirty; the solution creeps over the sides and the power decreases after a time. It is very well to say that "they are put away in a cupboard and there is an end of them." There is not an end—the solution runs over, or dries up, the dust and crystals clog the manganese and form a film over the zinc, and, more than all, the wet floor wastes two-thirds of the power. Keep the five or six cells of Smee in a case with a glass front, paraffin the top of the glass vessel (heating the glass first) if the solution creeps up, and don't let the paraffined wood bar that holds the plates get crystallised over. Another thing is that the Léclanché boasts of its considerable electromotive force, nearly half as much again as that of the Smee, but says nothing of the tremendous resistance of its porous cell, stony manganese, and saline solution. So much for that. After writing the letter in Vol. XXIII.

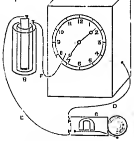
I was still troubled occasionally by a skip of one of the clocks. I thought of the condemnation awarded to electric clocks by electric authors, and felt inclined to give it up; but observing that a great improvement followed the lengthening of the time that the current is allowed to flow, and not being able to lengthen the time any further on account of the recoil of the old eight-day, I made a clock in which a uniformly rotating seconds' arbor drives an endless screw and conical pendulum—that is, a pendulum swinging (nearly) in a circle; by this contrivance I can give any desired length of "exposure" without fear of a double contact being made. Of course the current is all round the circuit the moment the points touch, but the armature requires an appreciable time to overcome its "inertia," or natural laziness. One second, however, is ample to avoid any chance of failure. I intend shortly to make a clock with a chronometer escape and a *remontoir* (which latter drives a heavy contact without any jerk or influence whatever on the escapement), in order to avoid the dust and fluff that clog the present one, which is too large to go under a glass-case, as the escape-wheel has 42 teeth and the pendulum revolves 42 times a minute, and is, therefore, just half a metre long. I shall continue the subject shortly.—IOSTEPHANOS.

6848

ELECTRICITY AND THE LOOM.—Many different kinds of "stop-motions" have been introduced into textile machinery for the purpose of stopping the loom automatically, when, from some cause or other, such as the breaking of a yarn, it begins to perform its work improperly. These purely mechanical contrivances are all more or less delicate, but an electrical stop-motion, not open to this objection, has been invented by Messrs Bullough and Smalley, and applied to the cotton machinery of Messrs. Howard and Bullough, Accrington. The current is supplied by a small magneto-electric machine, weighing a few pounds, and driven by a strap from the main shaft. The current from this machine is so applied that when contact is made by the breaking yarn, or other cause, it traverses an electro-magnet which causes a soft iron armature to drop into a ratchet wheel, whose motion being impeded, makes the strap work upon the loose pulley, and thus stops the machine. This stop-motion is applied to the carding engine, the drawing frame, and a roving frame. In the drawing frame the insulating property of dry cotton is taken advantage of in closing the circuit. This invention is giving great satisfaction to the cotton spinners of Lancashire. A full account of it was recently read before the Scientific and Mechanical Society of Manchester by Mr. W. H. Bailey.

[3122.]—Connecting Clock with Electric Bell.—I think "J. W. E." will find the following method of connecting an electric bell with a clock easier than the other arrangements which have been represented before, and trust it may not be too late to be of use. The rough sketch, I hope, will explain

Oct 78



itself:—A, clock; B, battery; C, bell. The wire D from one terminal of the bell is connected with any part of the works behind the clock; the wire E leads from the battery to the other terminal of the bell; and the wire F is placed at whatever hour the bell is wanted to ring. F has a little crook at the end, so that, when the hour hand of the clock touches it, it is carried round with it, the bell continuing to ring till the crook detaches itself by the hand going round—i.e., about 3 hours. I ought to mention that F is placed in such a manner that, although the hour hand touches it, the minute hand passes above it. This adjustment, though not so scientific as others, is most successful, and costs nothing.—MECHANICIAN.

EXPERIMENTS WITH THE ELECTRIC TOURNIQUET.*

Oct 4/78

IF an insulated electric tourniquet be put in communication with an electric machine, and if, when its velocity of rotation is considerable, it be covered with a bell jar, it will

* M. Bichat in the *Journal de Physique*.

stop. This (it is said) is because the air of the bell jar is electrified. If the bell jar be then touched with the hand, the tourniquet goes on again; and the explanation given is that the proximity of the hand has changed the electric distribution in the gas. The experiment succeeds very well when made under the conditions indicated. It is no longer so if we operate in the following manner:—

The tourniquet is placed at the centre of a glass plate, perforated at this point with a hole, by which communication can be effected with the electric machine, and it is covered with a glass bell jar. At this moment only the machine is set in action; the tourniquet does not move, or there is but a slight tendency perhaps to move, which is presently suppressed.

On looking at the instrument in darkness, one sees small "aigrettes," darting out from the extremities of the points, but from the metallic base of the tourniquet and of the rod which connects it with the machine. These aigrettes are directed towards the glass plate.

If now the experiment be re-commenced, the tourniquet being supported no longer by a metallic base, but by an insulating base (*e.g.*, sulphur), and if the wire connecting it with the machine be *perfectly* insulated, the tourniquet turns immediately on working the machine, and does not stop.

If in the first case the hand be brought near the bell jar, the tourniquet is set in motion, and in the second case the velocity of motion is considerably increased.

From these experiments it may be concluded, I believe, that if the tourniquet stops in the confined air when the experiment is made in the usual manner, this is not due to electrification of the air, as is generally said. One cannot understand, indeed, how the movement should be nil when the precaution is taken to cover the tourniquet with the bell jar before working the machine. Nor would it be easy to see why the tourniquet goes much better when supported by an insulating base. The electrification of the air must be much stronger in the second case than in the first. The explanation must be quite different. We shall reach it without difficulty if we suppose that for badly conducting bodies as well as for non-conductors, electricity tends to go towards the exterior surface of the bodies. If that is the case, the electricity supplied by the machine to the tourniquet placed under the bell jar tends to go towards the exterior along the glass plate, or producing on this plate phenomena of successive inductions on to the borders of the jar. What leads one to think it is so is the appearance of the aigrettes starting from the base of the tourniquet, and from the different points of the communicating wire.

When the tourniquet acts—that is, when it is supported by a well-insulating base, and in well-insulated communication with the machine—the electricity escapes in part by the points, and goes to fix itself on the walls of the bell jar along a circumference in the plane of the tourniquet. Thence it proceeds by degrees towards the exterior, according to the ordinary laws of propagation in badly-conducting bodies. The action of this electricity found on the walls must certainly become perceptible on the tourniquet. Then it will be that if the hand be brought near, or a good conductor communicating with the ground, the phenomenon of ordinary condensation will be produced. As a necessary consequence the delivery of the tourniquet will be augmented, and so the movement of rotation will become more rapid.

Taking these remarks into account along with those made by M. Mascart in his "Traité d'Electricité" (p. 175, &c.) all the peculiarities of the electric tourniquet may be accounted for. There is one other experiment I wish to cite, which well shows the difficulty experienced in making electricity penetrate directly into badly-conducting bodies. Take a cylindrical glass vessel, filled with spirit of turpentine, in which put an electric tourniquet; let this tourniquet communicate with the machine by means of a copper wire traversing the walls of the vessel at the lower part. Under these conditions the tourniquet does not act. The electricity expands on the exterior walls of the vessel. The experiment will succeed very well, on the other hand, if the tourniquet be placed in the vessel, supported by its sulphur base, and there be brought near it, by the open upper part of the vessel, the extremity of a metallic wire, perfectly insulated, in communication with the electric machine.

INTERFERENCE OF ELECTRIC SPARKS.—M. de Wall, finds that when two electric sparks are simultaneously produced at the extremities of a short tube smoked inside, the two discharges give figures of interference in the form of a black ring at the middle of the tube. If the sparks are not quite simultaneous the ring is slightly displaced. This method might serve to determine the velocity of sound. It can also be employed to measure the speed of propagation of electricity in a conductor by causing a spark to blaze forth at the middle, and another at the end of a long wire. It would be necessary, however, for this purpose, to obtain complete symmetry at the extremities of the tube, and to ensure that the two waves produced are identical. When the spark is from a battery discharge, the ring examined by microscope, is seen to be formed of several rings due to the oscillating discharge. From the position of these rings, it follows that the partial discharges are separated by an interval of about a quarter of a millionth of a second.

Oct 78

APPAREIL

ÉLECTRO-MÉDICAL A COURANT CONSTANT

DU DOCTEUR ONIMUS.

Nous avons récemment décrit quelques appareils électro-médicaux. Nous croyons utile de compléter nos précédentes notices en parlant d'un des systèmes les plus avantageux dont nos lecteurs apprécieront les avantages. La pile se compose d'un vase extérieur en verre A (fig. 2) renfermant un petit cylindre de zinc (Z) et une tige de cuivre terminée par une plaque de cuivre (c) (fig. 3). De plus, dans le milieu du vase et entouré par le zinc, plonge un tube en verre B ouvert par ses deux bouts, mais dont l'ouverture inférieure est fermée par une substance poreuse f (fig. 4). On a choisi à dessein, comme substance poreuse, la bourre du fusil, calibre 24, afin qu'il fût facile à tout le monde de la remplacer lorsqu'il en serait besoin. C'est dans ce tube en verre B que l'on met les cristaux de sulfate de cuivre, qui en remplissent environ la moitié, et la pile est alors représentée par la disposition de la fig. 5. Pour faire marcher la pile, il suffit de verser de l'eau ordinaire dans le vase extérieur et dans le tube où se trouvent les cristaux, de manière que le niveau de l'eau atteigne à peu près le bord supérieur du zinc, comme cela est représenté fig. 5, où la ligne $x\,y$ indique la hauteur que doit atteindre le niveau de l'eau. Deux pipettes pleines d'eau suffisent, en général, pour chaque élément. Le courant est établi d'une façon constante au bout de quelques heures, et la pile marche alors régulièrement pendant plusieurs mois. A de rares intervalles, il suffit d'ajouter quelques gouttes d'eau et d'examiner les tubes pour voir s'ils contiennent encore des cristaux de sulfate de cuivre et en remettre quelques-uns dans les tubes où ils ont disparu.

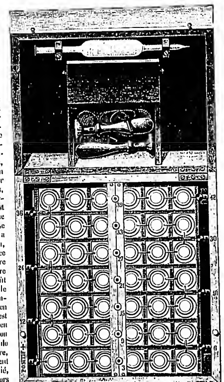

Fig. 1. — Disposition générale de l'appareil.

Les éléments sont disposés dans la boîte de manière à pouvoir augmenter ou diminuer le courant par trois éléments; lorsqu'on veut se servir de l'appareil, on place un des fils, le fil rouge par exemple, au point marqué + (positif), et l'autre fil est placé successivement dans les trous 3, 6, 9, 12, 42, selon que l'on veut avoir un courant de 3, 6, 9, 12... 42 éléments. Ce dernier fil représente toujours le pôle négatif.

Il est bon, lorsque la pile a été chargée pour la première fois, de fermer le courant pendant une heure, en faisant communiquer par un même fil la première pile (positive) avec la dernière (négative).

Cette disposition est celle des boîtes ordinaires; M. Brewer, le fabricant, construit également d'autres boîtes, plus élégantes et plus complètes, dans lesquelles les éléments sont réunis à un collecteur commun, en même temps qu'il se trouve avec ce collecteur un galvanomètre et un renverseur de courant.

Ces accessoires, qui n'ont d'utilité que dans certains cas, augmentent nécessairement le prix de l'appareil, et rendent l'entretien et le nettoyage de

nie les œufs de Saumon nécessaires aux travaux d'empoissonnement, et elle vient d'obtenir de la libéralité de la Commission supérieure d'être comprise pour un lot important (100 000 œufs) dans la récolte faite cette année sur les frayères de la rivière Mac Leod.

Depuis l'extension donnée à l'exploitation des minerais, les frayères de beaucoup de rivières californiennes ont été presqu'entièrement détruites; mais celles de la rivière Mac Leod, affluent du Pitt, ont conservé une richesse exceptionnelle. C'est donc sur les bords de cette rivière, au milieu de tribus indiennes d'une sympathie douteuse pour les *visages pâles* que M. le docteur Livingstone Stone se rend chaque année, dans le courant du mois d'août pour recueillir les œufs du *Salmo quinnat*, dont la fraye a lieu beaucoup plus tôt que celle du Saumon ordinaire.

La quantité d'œufs recueillis cette année par M. Stone est plus considérable encore que de coutume, et s'élève au chiffre de 7 millions environ. La plus grande partie de cette récolte est naturellement destinée aux nombreuses et importantes piscifactures des États-Unis; mais des lots considérables doivent être aussi expédiés à la Nouvelle-Zélande ainsi qu'en Europe : en Hollande, en Allemagne, enfin à la Société d'acclimatation de Paris.

Cette Société compte répartir l'envoi qui lui est destiné entre un certain nombre de ses membres le mieux en situation de donner aux œufs tous les soins nécessaires pour en mener l'éclosion à bonne fin, et assurer à l'expérience le plus de chance de réussite possible.

Dès le premier essai fait l'année dernière dans un pays voisin du nôtre, 25 000 des œufs reçus d'Amérique ont éclos et donné naissance à 25 000 alevins lesquels peuplent aujourd'hui les bassins d'un établissement qui, hélas! n'appartient plus à la France et qui s'occupe spécialement du réempoissonnement du Rhin.

L'entreprise actuellement tentée par la Société d'acclimatation ne paraît donc nullement irréalisable et l'on ne peut que faire des vœux pour la réussite de cette utile et intéressante expérience.

Raveret-Wattel.

ÉLECTROMÈTRE ENREGISTREUR

DE M. MASCART.

Un des problèmes les plus délicats que l'on puisse se poser dans l'enregistrement des observations météorologiques est certainement l'inscription de l'électricité atmosphérique et du magnétisme terrestre. Les quantités à mesurer sont tellement petites et la force qu'on peut demander aux appareils de mesures si faibles que, jusqu'à ces derniers temps, on a dû se borner à l'enregistrement photographique.

Ce procédé, parfait en théorie, présente dans la pratique de sérieux inconvénients. L'emploi de la photographie est en réalité, très-coûteux et exige un personnel spécial. Enfin, et surtout pour l'électricité atmosphérique, l'inscription est loin d'offrir la continuité sur laquelle on croirait pouvoir compter. Il faut, en effet, un temps notable pour que le faisceau lumineux incident produise une impression suffisante sur le papier photographique, parce que la sensibilité de ce papier n'est jamais très-grande, et si les mouvements de l'instrument sont rapides, l'impression ne se fait plus. Il semble donc qu'il reviendrait au même, dans tous les cas, de remplacer une inscription continue par des mesures faites de temps en temps, toutes les cinq minutes, par exemple. Si les variations sont rapides, l'inscription photographique est insuffisante; si elles sont lentes ou nulles, la continuité absolue des observations n'est plus nécessaire.

C'est en sacrifiant cette continuité d'inscription presque impossible à réaliser que M. Redier a pu, sur les indications de M. Mascart, construire un électromètre enregistreur purement mécanique, que l'on peut voir, fonctionner au pavillon météorologique de l'Exposition universelle, dans le jardin du Trocadéro.

L'instrument dont il s'agit d'enregistrer les indications est l'électromètre à quadrants de sir William Thomson. Sans vouloir entrer ici dans le détail de cet instrument, nous rappellerons qu'il se compose essentiellement d'une aiguille métallique en forme de 8, suspendue horizontalement par deux fils de cocon très-rapprochés qui forment une suspension bifilaire. L'aiguille se meut au-dessus de quatre quarts de cercle ou quadrants, reliés deux à deux en croix et communiquant avec les pôles opposés d'une pile, qui les charge d'électricités contraires. Suivant que l'aiguille en 8 est électrisée d'une manière ou de l'autre, elle est plus ou moins repoussée par une paire de quadrants et attirée l'un par l'autre; ces actions, contrariées par la force nécessaire pour tordre la suspension bifilaire, conduisent à une position d'équilibre, et l'on sait que la charge électrique de l'aiguille est proportionnelle au sinus de la déviation, ou à la déviation elle-même, tant que celle-ci ne dépasse pas quelques degrés.

Pour se mettre en équilibre avec l'appareil collecteur de l'électricité atmosphérique, l'aiguille porte à sa partie inférieure un fil de platine qui plonge dans un vase isolé contenant de l'acide sulfurique, liquide conducteur, dans lequel arrive en même temps le fil partant du collecteur, celui-ci est muni d'une flamme de gaz ou d'un écoulement continu d'eau, destinés à prendre le potentiel électrique de l'air en un point déterminé[1].

Si l'on veut inscrire par un procédé mécanique les déviations de l'aiguille, il est clair que l'on ne peut demander à cette dernière le moindre travail, car il suffit d'une force insignifiante pour la faire tourner. Dans le nouvel inscripteur, comme dans tous ceux que construit M. Redier, la force est empruntée à un rouage différentiel qui produit tout le travail, tandis qu'on ne demande à l'instrument

[1] Voir, pour les détails, le *Traité d'électricité statique* de M. Mascart, et un article sur l'électricité atmosphérique, publié par M. Angot dans l'*Annuaire de la Société Météorologique de France*, 1877, t. XXV, p. 155.

72

An apparatus recently devised by M. Celi, for experimenting on the action of electricity on living plants, consists of a large bell jar, into which electricity is admitted thus: An insulated metallic vessel is placed on a support about two metres high, and filled with water, which is then allowed to flow out by a very narrow tube. The vessel thus becomes charged with electricity, positive or negative, according to the state of the atmosphere (commonly the former). A collector, formed of metallic wire, is attached to this vessel, and penetrates into the bell jar, where it is connected with a crown of sharp metallic points for distributing the electricity. Under the bell jar are placed plants in vessels communicating with the ground. The bell jar is supported on glass, and air can be admitted or withdrawn through tubulures connected with a trompe. For comparison, similar plants to those under electric action are inclosed by another bell jar of the same size without application of electricity, but otherwise treated similarly. On July 30th M. Celi sowed some grains of maize in the manner described. On August 10th the plants in the electrified air had a length of 17c., while those in the unelectrified air were only 8c. Some researches on the composition of the air and the plants are in progress.

NOUVEAUX APPAREILS

ÉLECTRO-MÉDICAUX PORTATIFS

A RÉGULATEUR DES INTERMITTENCES

Oct PAR M. G. TROUVÉ 78

M. Trouvé a présenté récemment à la Société de physique deux interrupteurs de courant remplissant le même but, quoique basés sur des principes différents.

Le premier, par sa grande précision, est destiné plus particulièrement aux études physiologiques, car il donne à chaque seconde de temps le nombre d'intermittences à 1 centième de seconde près.

Le second, bien que ne pouvant rivaliser de précision avec le précédent, les donne à un quinzième de seconde près, ce qui est plus que suffisant pour la pratique médicale et répond à un desideratum souvent formulé.

On sait quelle importance il y aurait en faradisation à pouvoir régler à volonté le nombre des intermittences. Jusqu'à présent dans la pratique médicale ordinaire, on s'était contenté d'appareils munis du trembleur de Neef avec lequel on peut faire varier le nombre des intermittences entre des limites plus ou moins étendues, mais sans jamais en connaître le nombre.

Disons toutefois que des physiologistes, comme Duchesne de Boulogne, avaient cependant entrevu la nécessité de contrôler le nombre des intermittences ou le nombre des passages successifs du courant par chaque seconde de temps. Duchesne de Boulogne à cet effet avait fait disposer une pendule dont le balancier marquant la demi-seconde lui donnait à volonté une interruption ou deux par seconde. On utilisa également dans le même but le métronome et même la roue de Masson, mais, comme on le voit sans peine, ces divers systèmes d'interrupteurs avaient pour principaux inconvénients d'avoir un champ de variations trop restreint, d'être d'un prix élevé et de n'être pas transportables.

M. le docteur Onimus pour juger de l'influence des intermittences lentes ou rapides sur les mouvements du cœur et sur la contractilité musculaire dans certains cas de paralysie, s'adressa à M. Trouvé et voici l'appareil portatif qu'ils réalisèrent et que nous allons décrire.

Cet appareil d'induction à chariot (fig. 1) est constitué par une bobine inductrice indépendante des bobines induites, d'une pile hermétique Trouvé à renversement, des différents accessoires en usage en électrothérapie et d'un interrupteur spécial qui constitue la partie principale de l'appareil et fait l'objet de cette communication.

Cet interrupteur (fig. 2) se compose d'un cylindre divisé dans le sens de sa longueur en vingt parties; chaque partie est munie suivant la circonférence du cylindre d'un certain nombre de touches ou chevilles dont le nombre croît suivant une progres-

73

sion arithmétique, c'est-à-dire qu'à la première division il y a une touche ou cheville, à la seconde, deux · à la vingtième, vingt.

Le cylindre est mû par un mouvement d'horlogerie dont la vitesse se règle au moyen d'un régulateur, ou volant, à vitesse variable, ce qui permet de donner au cylindre le nombre de tours que l'on désire par seconde. Un stylet se meut à volonté parallèlement à l'axe du cylindre et peut être mis successivement en contact avec les différents nombres de touches, ce qui a pour but d'interrompre le courant autant de fois qu'il y a de touches à la position qu'il occupe.

Supposons que le stylet se trouve à la première division, où il n'y a qu'une touche; si le cylindre ne fait qu'un tour par seconde, le courant sera interrompu toutes les secondes et si on lui fait occuper successivement toutes les positions jusqu'à la vingtième on aura 2, 3, 4.... 20 interruptions du courant par seconde.

Donnant donc au cylindre une vitesse de 1, 2, 3, 4, 5, etc., tours par seconde, chaque touche sera multipliée par ce même nombre de tours et l'on obtiendra avec la plus grande précision, depuis une interruption jusqu'à cent, en passant par les intermédiaires, et l'on aura dans un temps donné un nombre d'interruptions donné.

Comme dans la marche du cylindre il serait impossible de lire les divisions et par suite placer le stylet au nombre voulu, on a placé parallèlement au cylindre une petite règle en ivoire divisée aussi en vingt parties qui correspondent aux divisions du cylindre, et en regard du stylet une petite aiguille que l'on met sur la division déterminée pour obtenir le nombre d'intermittences voulu.

Nous allons expliquer maintenant comment M. Trouvé est parvenu à obtenir que les passages successifs du courant principal ne varient pas en durée quelqu'en soit le nombre dans un temps donné. Cette précision dans la durée du passage successif du courant a une importance capitale; autrement, quelle comparaison établir entre des phénomènes qui varieraient entre eux justement comme la source qui les produirait?

A cet effet, le stylet E (fig. 3) comporte deux contacts A, B, en platine, superposés l'un à l'autre sur une plaque d'ébonite.

Ces contacts sont mis directement et à volonté dans le circuit au moyen d'un ressort à boudin. On comprend dès lors que si le contact supérieur B est dans le circuit, le passage du courant sera établi au moment même où le stylet sera soulevé par une touche du cylindre C, pour cesser immédiatement lorsque la touche sera passée.

Or, comme d'un côté, toutes les touches du cylindre ont la même vitesse, et que de l'autre, le stylet E et le ressort antagoniste D restent invariables, il en résulte que le temps du soulèvement du stylet reste lui-même invariable, quelque soit le nombre de soulèvements pour une révolution du cylindre.

Il en est de même du passage du courant qui est lié au soulèvement du stylet.

Les choses se passent autrement si la communication électrique a lieu par le contact A, car le passage du courant aura lieu pendant toute une révolution du cylindre, si le stylet est placé sur la première division, soit une seconde, par exemple, tandis que le stylet placé sur la division 20 du cylindre, le temps du passage des courants n'atteindra pas une vingtième de seconde. En un mot, la durée des passages successifs du courant variera comme le nombre même des intermittences, et c'est là le fait de tous les interrupteurs. Il résulte des deux effets que nous venons d'expliquer que pour produire des courants induits successifs, rigoureusement égaux, ce qui n'a lieu qu'avec cet appareil, il faudra établir la communication électrique avec le contact B et avec A, pour produire des courants continus intermittents, sur des courants induits variant en durée.

Les deux serre-fils 1 et 2, ont été disposés à cet effet pour placer le patient et l'interrupteur dans le circuit d'une batterie à courant constant et continu. Il suffit alors de mettre l'interrupteur en mouvement pour avoir des intermittences.

M. Trouvé s'en sert encore pour déterminer d'une manière irréfutable le nombre des vibrations que doit donner le trembleur d'une bobine de Ruhmkorff quelconque pour obtenir de suite de cette bobine le maximum d'effet.

Dans ce dernier cas, les contacts au lieu de se faire par les frotteurs métalliques A, B, se font dans une auge à mercure, comme dans l'interrupteur de Foucault.

Si on examine de près la figure 3, on s'aperçoit facilement que les contacts du stylet E avec les deux ressorts frotteurs A B, se font à glissements et tangentiellement, et que par conséquent la fermeture et l'ouverture du courant se font instantanément, sans passer par des variations de pression, conditions les plus favorables à la production des courants induits et des chocs musculaires isolés, nets et bien tranchés.

On recueille ces derniers en plaçant les cordons des électrodes en 5 et 6, pour l'extra-courant en 6 et 7 on recueille les induits; en 5 et 7, l'extra-courant et les induits réunis.

M. Trouvé, voulant doter la pratique médicale d'un appareil remplissant les mêmes conditions, mais qui fut tout à fait à la portée de tous les praticiens, sous le rapport du prix et du volume, fit présenter à l'Académie de médecine, par M. le professeur Gavarret, l'appareil que nous allons également décrire (fig. 4). Voici à ce sujet la note remise pour le bulletin de l'Académie par le savant professeur lui-même, séance du 5 juin 1877.

« M. Gavarret présente, de la part de M. Trouvé, un nouvel appareil d'induction destiné à la pratique médicale; cet appareil très-portatif réalise un perfectionnement considérable. »

THE ELECTRICAL DEPARTMENT IN THE MECHANICS' FAIR, BOSTON, MASS.

Groves 78

At the Mechanics' Fair held four years ago in Boston there were nine entries classed under the head of electrical inventions; to-day there are eighteen. This increase marks the great advance we are making in the application of electricity to the useful arts.

Even in the approach to the exhibition building, which is opposite the Boston and Providence depot, corner of Columbus avenue and Pleasant street, one face is illuminated at night by an electric light, which simulates the white gleam of moonlight, throwing dark shadows and enabling one to see to pick up a pin on the sidewalk with perfect ease.

The illumination of the main building by electricity is the most important feature of the exhibition. One side of the large hall is lighted by five lamps which are run by the Wallace Farmer machine, and the opposite side is lit by four lamps run by the Brush machine. The Wallace Farmer lights are provided with plate carbons two inches by five or six in area. The voltaic arc plays across the smaller side. From three to five lamps are run upon one circuit by the Wallace Farmer machine. If one light should happen to go out, the others in the circuit are not extinguished, for the plate carbons close together and the light is relit. These lights necessarily flicker to a certain extent; they are, however, steadier than would be imagined when the great play of the voltaic arcs in each lamp is considered. It has been demonstrated at the fair that five lights at least can be furnished on one circuit by the Wallace Farmer method. This in itself is a decided achievement.

The Brush lamp makes use of what may be called the pencil carbon points in contradistinction to the Wallace Farmer carbon plates. Each of the Brush machines furnishes four lights, which are fed by four different currents running on two conductors to each lamp. The Brush lights appear to be steadier than the Wallace Farmer lights, but not so powerful. The question of the amount of power used by both machines and the resistances of the circuits of both machines enter, however, in the question of the amount of current generated which produces the lights. The Brush lamp is certainly very steady in its action. The Wallace Farmer lamp and the Brush lamp do not differ in principle with the exception of the use of broad plates by the one and pencils by the other. The carbons of the Brush light are electro-plated with copper, which, it is claimed, prevents the heating of the carbon below the point of burning and regulates the consumption at the points.

We have said that both lamps do not differ in principle. In the Brush lamp the upper carbon is lifted by the movable core of a straight electro-magnet; in the Wallace Farmer by the armature of a horseshoe magnet; and practically the same mechanical device is used in both lamps to prevent the upper carbon from falling when the circuit is made. In the Art Gallery the two rival lamps confront each other, and one can judge better there of the relative brilliancy of the two. The details of the pictures are clearly seen in the brilliant lights, which are softened by heavy ground glass or opal shades. Great interest is manifested in these lights, which seem to be the prominent ones before the American public.

No less than twenty different electrical lamps were exhibited this summer at the Paris Exhibition; and three hundred lamps were lit during the nights of the past summer in the French capital. The Jablochkoff candle has not made its way to this side of the water, and American makers of dynamo-electric machines are attacking the problem of electric lighting by means totally different from those used in France. While we use the continuous current machines the French makers are altering their machines into alternate current machines, so as to obviate the unequal wearing away of the positive and negative carbons. The Jablochkoff candle dispenses with a regulator and thus enables more than one light to be produced by the same alternating current. The American regulators exhibited at the Mechanics' Fair would not work with an alternating machine.

The subject of electric illumination is evidently in its infancy; four years ago, however, the Mechanics' Fair could not have been so satisfactorily lighted as it is every night at the present time by the Brush machines and the Wallace Farmer machines.

The next important invention, and by some considered the most important, is the telephone. Both the Bell telephone and the telephones of the Western Union and Gold and Stock Company are placed on exhibition. The forms of the Bell telephone are well known; both the hand and the box instrument are at the fair, and are connected with the various telephone dispatch companies in and out of Boston, so that one can converse about the fair with one's distant friends. It appears from various trials that a message can be heard better from Cambridge than from a neighboring room in the exhibition building; there is a certain condition of outside resistance beyond the mere resistance of the circuit which seems to give the best effect. In the Gold and Stock Company exhibit can be seen and heard the various forms of Phelps' telephones and also Edison's carbon transmitter. The latter, in combination with a Bell or Phelps telephone, gives the best effect of any telephones or telephonic combinations. It is claimed that the New England Telephone Company (Bell's patent) have succeeded in improving their methods of communication in cities and towns. The same company also exhibit a new and very sensitive call. It is marvelous how quickly a new industry has sprung up with the introduction of the telephone! New forms of flexible telephone cords, provided with binding ends, which obviate the expensive terminals now in use, are exhibited by Mr. Hale, and are practical improvements. Holding & Co. also exhibit enamel covered wire for telephones and electro-magnets in general. Copper wire is coated with a very thin black insulating preparation which is said to stand heat and moisture remarkably well. More turns of this wire can thus be wound upon a given bobbin or magnet than of silk or cotton covered wire.

Edison's electric pen, which is well known to readers of this journal, has a liberal space devoted to it in the exhibition. Many specimens of its work are given, including some fine writing by Edison himself.

An apparatus for lighting street lamps and gas jets in fire engine houses is shown by Mr. Stevens; it seems to be a very practical device, and superior to that which has lately attracted much attention in London. Mr. Stevens makes use of the direct current to turn on the gas, and of the spark produced by the extra current to light it. Many forms of hotel electric annunciators and burglar alarms are exhibited. The exhibition building is protected from fire by the automatic electric fire signal company. The principle of their device consists in the use of a small cell which expands by heat and completes an electric circuit, which thereupon gives an alarm. If electricity could be used to heat the buildings, it could be said to afford in itself both the means of preservation and destruction of the fair.

Nov 78

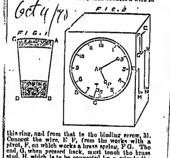
Longitude by Telegraph.—As a specimen of the precision now attainable in the determination of longitudes by galvanic signals, we may quote the three results, obtained at different times, and in different ways, for the difference of longitude of Greenwich Observatory and Harvard Observatory, Cambridge, Mass. They are as follows:—

	h.	m.	s.
In 1866, by Anglo-American Cables ...	4	44	31·00
In 1870, by French Cables, to Dixbury	4	44	30·99
In 1872, by French Cable, to St. Pierre	4	44	30·96

[14122.]—Connecting Clock with Electric Bell.—Solder a piece of platinum round the point of the small hand of the clock, and fasten or solder a piece of copper wire on to any part of the framework of the works, so that the wire will be in electric connection with the piece of platinum on the small hand; cut a piece of tin or ferrotype in the shape of Fig. 1; solder pieces of platinum foil on the parts denoted by the shading; file the end, A C, so that it slides easily between the brass ring, D C B, which holds the face, and the face; then connect a wire to

Oct 4/78

FIG. 1 FIG. 2



this ring, and from that to the binding screw, M. Connect the wire, E P, from the works with a pivot, F, on which works a brass spring, F G. The end, G, when pressed back, must touch the brass stud, H, which is to be connected by a wire to the binding screw, N. One pole of the battery (preferably a Léclanché) must be connected with N, the other being connected with one binding screw of the bell; the other screw of which must be connected with M. The action is as follows:—Having first pushed G on to H, and slipped the piece T C to the hour at which the bell is required to ring, the platinum point, P, coming in contact with the piece T C completes the circuit, and thereby rings the bell, which may then be stopped by slipping F G off H. Care must be taken that the point P, while making good contact, slides easily over H D (Fig. 1), or else, of course, the clock will stop. It is better to bevel the side, G D, to make it easier for the small hand to slide over it. The length, H D, depends on the time you want the bell to ring. Mine is just as wide as 2 minutes' space, and will ring for 24 if I don't stop it. I have had it for 4 months, and it has waked me every morning. I hope this will suit "J. W. E."—A. Wright.

Ingenious Application of Electricity in the Arts.—A new and useful application of electricity has been made by an American inventor to the apparatus for reeling silk from the cocoon. The delicate filaments of silk are carried over wire arms, which are so nicely balanced that they do not press against the silk strongly enough to break it, and in this relation a current is kept open; but, if the filament breaks, the arm falls, the circuit is closed, and an electro-magnet instantly stops the reel until the break is repaired. As the work is now done, the detection of a broken filament depends entirely upon the skill of the workmen, and the work must be carried on slowly that the eye can note any break, while with this automatic stop it is said the labour will be much more rapidly done, and a more uniform thread produced. The invention is being introduced into France and Italy, the two great silk-producing countries of Europe. Dec 78

Jan THE TELECTROSCOPE. 79

M. SENLECQ, of Ardres, has recently submitted to the examination of MM. du Moncel and Hallez d'Arros a plan of an apparatus intended to reproduce telegraphically at a distance the images obtained in the camera obscura. This apparatus will be based on the property possessed by selenium of offering a variable and very sensitive electrical resistance according to the different gradations of light. The apparatus will consist of an ordinary camera obscura containing at the focus an unpolished glass and any system of autographic telegraphic transmission; the tracing point of the transmitter intended to traverse the surface of the unpolished glass will be formed of a small piece of selenium held by two springs acting as pincers, insulated and connected, one with a pile, the other with the line. The point of selenium will form the circuit. In gliding over the surface, more or less lightened up, of the unpolished glass, this point will communicate, in different degrees and with great sensitiveness, the vibrations of the light. The receiver will also be a tracing point of blacklead or pencil for drawing very finely, connected with a very thin plate of soft iron, held almost as in the Bell telephone, and vibrating before an electro-magnet, governed by the irregular current emitted in the line. This pencil, supporting a sheet of paper arranged so as to receive the impression of the image produced in the camera obscura, will translate the vibrations of the metallic plate by a more or less pronounced pressure on that sheet of paper. Should the selenium tracing-point run over a light surface the current will increase in intensity, the electro-magnet of the receiver will attract to it with greater force the vibrating plate, and the pencil will exert less pressure on the paper. The line thus formed will be scarcely, if at all, visible; the contrary will be the case if the surface be obscure, for, the resistance of the current increasing, the attraction of the magnet will diminish, and the pencil, pressing more on the paper, will leave upon it a darker line. M. Senlecq thinks he will succeed in simplifying this apparatus by suppressing the electro-magnet and collecting directly on the paper by means of a particular composition the different gradations of tints proportional to the intensity of the electric current.

MECHANICS.

January 21, 1882.

Electric Clocks.

Mr. Jones Hamblet, manager of the time service of the Western Union Telegraph Co., delivered a lecture on electrical clocks on last Wednesday evening before the New York Electrical Society. The speaker described his various experiments in the construction of his clock, the wires of which extend in five directions through this city and Brooklyn. He stated that the correct operation of this piece of mechanism depended, first, upon its pendulum, the most sensitive power in all mechanics, then upon its battery, and finally upon its dial. When these parts are perfectly made the success of the electrical clock could not be denied. The experiments of the past ten years directed toward this end had resulted in an almost perfect clock, in proof of which the lecturer read from the correspondence of parties now using instruments constructed in accordance with the most recent discoveries in this branch of science. He illustrated the making of a clock by a stereopticon display. The greatest number of dials manipulated by a single clock is 58, placed in the various apartments of the Boston High School. He described the New York time service and its results, and estimated that not more than a difference of three-tenths of a second ever existed between its record and those of the Washington and Cambridge observatories. This difference was mainly due to the sudden changes of temperature, and he prophesied that in a very short time a remedy would be provided for it. After he had concluded his lecture, he introduced to to the society Prof. Cleveland Abbey, of the Signal Service Bureau at Washington. Prof. Abbey stated that he had just been advised of the action of the American Institute of Civil Engineers calling for a national convention of engineers, business men, railroad men, and scientific societies generally, for the establishment of national conformity in time. He considered this a most sensible and important action. He didn't see how it mattered to any man whether his watch said 5, 10 or 1 o'clock when he got up in the morning, nor could he conceive any reason why we should have to count up 55 minutes every time we made a business engagement in Chicago, when it was just as easy for our watches everywhere to agree. The great railroad lines of the country had 70 different standard times, and the only reason they gave for such "standard confusion" was that it was difficult to alter an old method—a small reason for so bad a plan. He proposed, in lieu of a single national time, a compromise of three standard times—Philadelphia time for the Atlantic Coast, St. Louis time for the Mississippi Valley and San Francisco time for the Pacific Coast. He indorsed the action of the American Institute of Civil Engineers, and hoped it would lead to a radical reformation of this absurd confusion.

Roue phonique de M. Paul Lacour

(Suite)

Dans notre précédent article, nous avons dit que la roue phonique était susceptible de nombreuses applications; nous allons, aujourd'hui, étudier les principales.

Application comme chronographe. — Les chronographes sont, comme on le sait, des appareils destinés à mesurer de très-petits intervalles de temps écoulés entre deux ou plusieurs phases d'un phénomène que l'on veut étudier. Pour obtenir cette mesure, il est essentiel d'obtenir de la part du moteur appelé à fournir les indications un mouvement parfaitement uniforme, et nous avons vu que la roue phonique résolvait précisément ce problème, et cela de la manière la plus simple.

Si on calcule, d'après les données que nous avons exposées dans le précédent article, la limite de l'erreur qui peut résulter de ce système de mesure on reconnaît qu'elle est plus petite que 1/25000.

Application comme horloge. — Le mode d'action de la roue phonique la rend susceptible d'être appliquée à l'horlogerie dans certains cas. En effet, comme trois systèmes d'appareils concourent à son fonctionnement, et que ces systèmes peuvent être placés à telle distance que l'on veut, on peut placer, par exemple, l'appareil vibrateur dans des conditions telles que les causes extérieures qui agissent sur les horloges de précision se trouvent soustraites à ces influences, et alors l'appareil compteur dirigé par la roue phonique peut fournir des indications rigoureusement précises en tel endroit qu'il convient.

En second lieu, plusieurs roues phoniques pouvant être introduites dans le même circuit ou commandées les unes par les autres, on pourra avoir plusieurs horloges marchant tout à fait synchroniquement.

Enfin, l'aiguille des secondes, ou toute autre marchant plus rapidement encore, pourra effectuer son mouvement sans secousse et d'une manière parfaitement régulière dans toute sa révolution.

Application à la détermination du nombre des vibrations d'un son. — La roue phonique peut être avantageusement substituée à la sirène pour la détermination du nombre des vibrations d'un son. Pour obtenir ce résultat, l'axe de la roue phonique porte une vis sans fin qui fait fonctionner un compteur comme on le voit fig. 10. Pour faciliter l'observation, le compteur peut être disposé d'après le système décimal ou centésimal, de manière que la différence entre deux observations donne directement le nombre d'ondes qui ont parcouru l'électro-aimant de la roue phonique pendant le temps qui s'est écoulé entre ces observations.

L'expérience se fait d'une manière différente suivant les conditions de la source sonore.

Si le corps sonore peut se maintenir longtemps en vibration, on peut l'employer lui-même comme organe transmetteur du courant, et le compteur, en indi-

had learned to adore him. Mr. Musters was a fearless explorer, and a man of unfailing tact and winning manners. Two or three years ago Mr. Musters returned from Bolivia, with which little-known country he had made a thorough acquaintance, and had, we believe, collected material for an interesting work. He recently received the appointment of Consul at Mozambique, and was to have left this month for his post, from which, he was delighted to think, he would be able to do some valuable exploring work in the African interior. By his death Her Majesty has lost a faithful and able servant, and science an eager explorer. Musters was loved by every one who had the pleasure of his acquaintance.

THE prosecution of marine surveys on the coasts of India has been for a long time much hampered by the want of a proper surveying steamer, and we are glad to learn from a Bombay paper that a new vessel—the *Investigator*—has just been launched, which will supply the defect. The steamer is well provided with all the necessary appliances for chart-making, deep-sea sounding, &c.

THE November number of the *Bulletin* of the French Geographical Society contains Dr. Jules Crevaux's account of his exploration in the interior of French Guiana in 1877. Dr. Crevaux, with little assistance and in the face of not a few difficulties, ascended the River Maroni, and striking the River Yary, traced its course to its junction with the Amazon. The two main results of his journey are the crossing for the first time of the Tumuc-Homac chain at the level of the sources of the Maroni, and the discovery and complete delineation of the Yary, an important affluent of the Amazon. The Maroni he describes as a fine river of about 140 leagues in length, with a breadth of 1,200 to 1,500 metres at 20 leagues above its mouth, and from 400 to 500 at 90 leagues. The River Yary, Dr. Crevaux considers as more important than the Maroni; it is 150 leagues long, and both rivers are much obstructed by falls and cataracts. Dr. Crevaux gives some very useful notes on the forests of Guiana and the different species of trees which they contain. The highest summits of the Tumuc-Humac range do not exceed 400 metres above sea-level. In summing up his observations on the geology of the region traversed, he says that all the formations met with from the mouth of the Maroni to that of the Yary have an ancient physiognomy. They may be

with the aid of reindeers or dogs. Herr Sibiriakoff has telegraphed to Baron Fredericks, asking him to send a party to the assistance of the Swedish Expedition. He has received a letter from Dr. Lindemann, of Bremen, in which the former says that at the coast where the *Vega* is believed to be lying there is a large native village, and from this village the nearest post of white merchants is distant only about 200 English miles, which may be traversed in winter in three or four days.

A REPORT has been received of a journey by Mr. Haber in the north-west of the Chinese province of Szuchuen. The original intention was to examine, between Suchow and Kiating, the River Tatu, which falls into the Yangtze-Kiang, and then to cross the mountains from Kiating to Fu-lin in long. 103°. At Fu-lin, however, Mr. Haber was induced to extend his exertions into the country further west, and he travelled onwards to a place called Tzu-Tati, the head-quarters of a Sifan chief. Here he heard of the existence of a mountain path to Ta-chien-lu, the French missionary station lying nearest to Tibet. After travelling three days through pine forests, the mountain range was crossed by a snowy pass, and on the northern slope yaks were found grazing, and many slates, inscribed with Sanskrit characters, were noticed. The appearance and language of the people also pointed to the fact that though Tibet proper is many hundred miles west of this point, yet tribes of the Tibetan race and language extend up to the banks of the Tato River. This confirms the views already expressed by Mr. T. T. Cooper and other travellers.

THE *Japan Gazette* translates an article of some interest from the *Osaka Nippo*, on the subject of Japanese relations with Corea. After commenting on the progress made by Japan during the past few years, the writer remarks that "the Coreans, on the contrary, obstinately cling to the customs of Gio, Wo, and Shin, three Chinese sages who lived 3,000 years ago, and they believe their country is a part of Paradise, next in rank to China, and that western countries are inhabited by barbarians and savages."

COUNT WILCZEK and Lieut. Weyprecht intend to visit the northern coast of Novaya Zemlya in the course of this year, and will remain at that station for a twelvemonth in order to make a series of exact magnetic, electric, hydrographical, and meteorological observa-

79

A Practical Application of the Electric Current. Jan 4/79

A very important application of the electric current, says the British *Trade Journal*, is now being carried out by Sir William Armstrong on his estate. A volume of water descending at the outfall of a Northumberland lake has been utilized by the interposition of a turbine, by means of which the requisite revolutions are given to a dynamo electric machine. The electric current thus generated is conveyed through a stout copper wire to the private residence of Sir William at Cragside—a distance of about a mile and a half. The current is there conducted through a lamp, in which the regularity of the light is maintained by clockwork, subject to the control of an electro-magnet, which magnet reflects the strength or weakness of the current, so as to regulate the distance between the points of the carbon electrodes. It has been found necessary to provide a second wire to take the return current, so that the first cost of the light is somewhat large, but the working expense is very small. In addition to this use of the electric current as a source of light, Sir W. Armstrong intends to avail himself of the power thus brought into his house by applying it to several domestic purposes. This is to be accomplished by means of an electric engine situated in or near the house, and receiving the current transmitted from the machine at the lake outfall. In this way Sir William will be able to make a more constant use of what may be termed his electrical "plant," and thus may look forward to a satisfactory result in an economical respect. This example of the conversion and transmission of power will be viewed with great interest, the distance of a mile and a half being sufficient to indicate a much more extended sphere of action for the electric current than has hitherto been found practicable.

80

An electro-magnetic railway-ticket counter, to indicate the number of passengers going by a particular train, and so the number of carriages of each class required, has recently been adopted at the station of the Kaiser Ferdinand's Nordbahn, in Vienna. The date press of each of the three ticket boxes is furnished with an electric contact, actuated each time a ticket is pushed in to be stamped. Three lines connect the presses with a clock-shaped counter in the office, where the train is arranged, having discs with numbers and pointers, so that the number of passengers booked can be seen at once. The arrangement conduces to promptness in ordinary circumstances, and where great crowds are travelling, successive trains can be quickly despatched without overloading with passengers. Mayer and Wolf, of Vienna, supplied the apparatus. Jan 79

THE VOLTAIC PENCIL OF M. BELLET.—According to *l'Electricité*, means have been found to engrave upon stone or metal by the effect of a voltaic arc produced from the point of a pencil. It is said that, by these means, an artist can himself reproduce, immediately and without the intervention of any skilled workman or mechanic, the most delicate and complicated designs. If this statement can be confirmed, it will be of no small interest to the proprietors of illustrated papers. Feb 15/79

THE VOLTAIC PENCIL. Feb 1/79

There is at the present time scarcely a single branch of industry to which electricity is not lending its aid. Art, however, has thus far received but little benefit from this source, if we except the application of electricity to electro-metallurgy. We are pleased to learn, then, that an important discovery has just been made at Paris by M. Bellet, whose invention consists of a voltaic pencil, by the use of which designers and draughtsmen will be enabled to dispense entirely with the aid of the engraver. The editors of *Electricité* state that they have examined beautiful proofs of lithographs and etchings obtained, without the use of the graver, by the effect of a voltaic arc produced at the point of an ordinary lead pencil. Encouraged by his success the inventor has taken out patents in various countries, and a company has been formed to carry out the process, which will soon be placed before the public. At present there are being prepared models of a series of apparatus which will allow any artist, however ignorant of the mysteries of electricity, to reproduce immediately, and without the aid of any artisan, the most delicate and complicated drawings; and this, too, by a very simple process and at a very moderate price. By a slight modification of the system there may be produced: (1) Stencils analogous to those produced by the Edison pen; (2) lithographs; (3) etchings; (4) stereotypes for typographical work. The initiators of this discovery are confident that an entire revolution will take place in the process of illustrating papers by means of their electrography.

ELECTRICAL CLOCK DIALS. Feb 1/79

M. RECORDON, of Paris, has since been manufacturing illuminated dials on an entirely different principle from those produced by the use of chemicals. His device is this: A Geissler tube containing a gas which gives a brilliant light is placed on the dial; a battery about the size of a thimble is attached as an ornament to the watch chain, and a miniature induction coil is also hidden in the latter. When it becomes desirable to consult the watch in the dark, a spring is pressed, the current passes into the coil, then into the Geissler tube, and illuminates the dial. The portable battery used for this purpose is that of Trouvé, which, in a small compass, has considerable strength. Reduced to the size of a thimble, it is still sufficiently strong in its action to last a year. M. Recordon also applies the same principle to the illumination of clock faces.

place under circumstances and conditions special to themselves, and which do not exist in the case of industrial or other works. These arise in part from the paramount necessity of providing in the lighthouse an illumination of the most perfect character, and abundant in intensity, as well as of providing an amount of extra plant to guard against any cessation in the illumination. The generally isolated situation of the lighthouse also adds to the cost of the materials employed, and causes the personal staff employed to be of a more skilled class, than where assistance in the matter of repairs is readily available. Any comparison, on purely economical grounds, between the electric illumination in lighthouses and in industrial works, must necessarily be unfavourable to the former.

(TO BE CONTINUED.)

THE TROUVE ELECTRICAL POLYSCOPE AND SAFETY LAMP, FOR POWDER MAGAZINES, MINES, DIVERS, CORAL AND OYSTER SEEKERS, &c.

The electrical polyscope, or the modification of it which constitutes the safety lamp, is composed of:—

1st. A reservoir in which dynamical electricity may be stored up, *i.e.*, a secondary battery of M. Planté.

2ndly. A series of reflectors, with or without mirrors, adapted for various modes of illumination, whether it be that requisite for a powder magazine, or that adapted for cavities in the animal organism. These reflectors are all parabolic. The reflecting lamp intended for powder magazines is provided with a double transparent envelope, which affords the requisite protection.

3rdly. A battery of four Trouvé-Calland elements, for the purpose of charging the reservoir, together with various conductors and a stand, to which may be attached the reflectors of the safety lamp.

4thly. Of a special resistance coil or regulator of extreme simplicity, intended to regulate the flow of electricity from the reservoir. We use here the term "flow" of electricity, because those who are acquainted with secondary batteries will understand how analogous these are to a hydrostatic reservoir. The adjustment obtained by means of this regulator is so perfect that platinum wires, varying in diameter from 1-15th millimetre to 1½ millimetre, may be raised to a temperature approaching the point of fusion of the metal without any danger of actually reaching this point.

5thly. A double-circuit galvanometer in which the electromotive force of the reservoir and that of the battery are in opposition. Thanks to this simple and ingenious arrangement, the operator or the practitioner can always know, on the one hand, the capability of the battery to effect the charge of the reservoir, and, on the other hand, the degree to which the reservoir is actually charged. Thus, when the reservoir is completely exhausted, the needle returns to its initial position, *i.e.*, to a *minimum* deflection of 30°. Should the deflection be less than this, it may be concluded that either sulphate of copper or a zinc element requires to be supplied.

The utility of the apparatus in the case of powder magazines will readily be understood. At the entrance to each magazine is placed a box containing three or four Trouvé-Calland elements; and on the box is stood the reservoir or secondary battery, the charge of which is to be maintained by the primary elements in question. Whenever the artillerist requires to enter the magazine, he takes the reservoir in one hand, and in the other the stand which carries the reflector; and, the moment he completes the circuit by means of the key attached to the stand, the darkness is dispelled by the magic light of this ingenious apparatus, a light which, if necessary, will last for several consecutive hours. In case of accident, the artillerist would carry with him a duplicate reflector, which could be substituted for the other upon the stand.

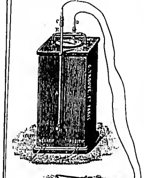

FIG. 1.

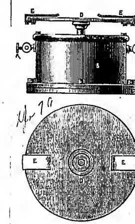
On leaving the magazine, he would replace the secondary...

81

AN ELECTRICAL MOUNTING TABLE.

[15534.]—I VENTURE to inclose tracing and brief description of an electrical mounting table, devised



Ap 79

by me last winter, thinking that it may be likely to interest some of your readers who, like myself, mount their own objects for the microscope, and like to have both hands free while doing it. I found it irksome to have one hand occupied in turning the table, so set about making a table that would work independently of any manual help. I use a small bichromate battery, and find that by raising or lowering the zinc I can very evenly regulate my speed. Upon connecting the two battery wires with the terminals A, a current traverses the electro-magnet pivoted upon the shaft C. It then turns towards the highest point in the nearest inclined armature, of which there are several, cast in the wall of the casting B. Before it reaches quite the top of incline, the current ceases, and with it any retarding action upon the revolving magnet. Acquired momentum carries it past this point, when the current again excites the magnet, which commences to climb the next. A continuous rotatory motion is thus imparted to the table, and any slide or other object held under the steel clips E. I shall be glad to give you any further details. The table is provisionally registered. F. M. Rogers.

29, Moorgate Station Buildings, E.C.
March 31, 1879.

82

AN ELECTRIC TELESCOPE.

[15571.]—It may be of interest to your readers to know the details of some experiments on which I have been engaged during the last three months, with the object of transmitting a luminous image by electricity.

To transmit light alone all that is required is a battery circuit with a piece of selenium introduced at the transmitting end, the resistance of which falling as it is exposed to light increases the strength of the current, and renders a piece of platinum incandescent at the receiving end thus reproducing the light at the distant station.

By using a number of circuits, each containing selenium and platinum arranged at each end, just as the rods and cones are in the retina, the selenium end being exposed in a camera, I have succeeded in transmitting built-up images of very simple luminous objects.

Feb 7/78

Correspondence.

[We do not hold ourselves responsible for the opinions of our correspondents.]

CLERAC'S TUBE.

To the Editor of THE TELEGRAPHIC JOURNAL.

DEAR SIR,—Enclosed I send you official communications just received from the French Government relative to Clerac's Tube.

Sincerely yours,

3rd Feb., 1879. D. E. HUGHES.

"Paris, le 1er Février, 1879.

"MONSIEUR LE PROFESSEUR,—Conformément au désir que vous m'avez exprimé, je vous adresse ci-joint une série de documents établissant que les tubes de résistance ou rhéostats à charbon imaginés par Monsieur Clérac, remontent certainement à une date antérieure au 4 Mars, 1866.

"Recevez, Monsieur le Professeur, l'assurance de ma considération très distinguée,

"COCHERY,

"Le sous Secrétaire d'Etat des Finances.

"Monsieur le Professor Hughes,

"94, Great Portland Street, London, W."

The following is a translation of the above letter:—

"Paris, Feb. 1, 1879.

"MONSIEUR LE PROFESSOR,—Conformably to the desire that you have expressed to me, I send you herewith a series of documents establishing that the resistance tubes or carbon rheostats, invented by M. Clerac, go back certainly to a date anterior to the 4th March, 1866.

"Receive, M. le Professor, the assurance of my very distinguished consideration,

"COCHERY,

"The Under-Secretary of State for Finance.

"(Now Minister of Posts and Telegraphs.)

"Professor Hughes,

"94, Great Portland Street, London, W."

[Here follows the original letter from Professor Hughes to M. Clerac respecting his tubes, which we published in the Correspondence of our last number. It bears the Paris postmark for March 10, 1866, on its back.—ED. T. J.]

The other documents are:—

"Paris, January 27, 1879.

"My dear M. Clerac,—It was in 1866 that I delivered to the Administration des Telegraphes the first Hughes' apparatus that I constructed. It was equally in the same year that, I was nominated a member of the Comité de Perfectionnement de Lignes Télégraphiques, of which Professor Hughes was also a member. These dates make me absolutely certain that Prof. Hughes spoke about and described to me, either at the end of 1865 or in the beginning of 1866, your rheostat formed of powdered carbon or pulverised plumbago, which you mixed more or less with other substances, and which you compressed more or less. I recollect perfectly this little tube which I hold in my hands, and in answer to my question, 'Can this serve as a standard of resistance?' Professor Hughes replied that you had found that the conductivity was variable with the pressure. (M. Hughes m'a repondu que vous aviez reconnu que la conductibilite etait variable avec la pression.)

"All this, my dear M. Clerac, I recollect perfectly, and I attest it willingly to you by this letter, begging you to believe me,

"Votre plus dévoué,

"E. HARDY,

"Ingenieur-Electrician.

"5, Avenue de la Motte Piquet, Paris."

"Paris, January 27, 1879.

"I, the undersigned, declare that I constructed in the course of the year 1873, with carbon, metallic, and other powders, agglomerated by means of fatty bodies, sundry resistance apparatus, which had for their starting point (qui avaient pour point de départ) the economical rheostats, formed of powdered carbon compressed in insulating tubes by regulating screws, invented anteriorly by M. Clerac.

"(Signed) BEAUFILS,

"Chemist, Chargé du Laboratoire à la Reception du Material."

"Paris, January 27th, 1879.

"L'Inspecteur-ingenieur, Chargé du Service de la Reception du Materiel des Telegraphes, certifies to having made use in 1873 for to establish leakages (etablir des derivation) on lines from Paris to Marseilles, some of the resistance apparatus which form the subject of M. Beaufils' certificate.

"(Signed) LAGARD."

"Paris, January 28th, 1879.

"The undersigned certify to having executed towards the end of the year 1865, and during the year 1866, according to the instructions of M. Clerac, and under his direction, certain rheostats of powdered charcoal and graphite, dried, and compressed in glass and wooden tubes by aid of a regulating screw, whose degree of pressure permitted the resistance to be varied.

"This work was done in the premises set apart for the course of instruction on the Hughes' apparatus at the seat of the Administration des Télégraphes, Paris.

"(Signed)

"L. MANDROUX, L. RAULT, L. BARDEZ,"

Agents speciaux des Telegraphes a l'Administration Telegraphique.

The following letters on the above subject have also been addressed to the TELEGRAPHIC JOURNAL.

SIR,—Prof. Barrett's arguments would be more readily understood as coming from a lawyer rather than from a man of science. He pretends that since I did not speak of the variation of resistance with difference of pressure, in my note of 1874, to the *Journal Telegraphique* of Berne, it was because I was ignorant of the phenomenon. To that the reply is easy; I had no call in a note of several lines to give the theory of my apparatus, but only to set right an allegation of M. Zetzsche who attributed that invention to a German. It will suffice to re-read my note and the article to which it replied for to convince any one that there was no need then either to describe the article or to give the theory of it.

If now any one examines my tubes, he will be led to ask himself why I employed pressure screws, if it was

83

not for the purpose of varying the compression of the powder until the resistance sought is obtained.

Further—and this is a criticism that I have myself addressed to my inventions since the beginning—as Prof. Hughes will be able to recall—the variations of temperature in dilating or in contracting the glass or wood, produced variations of the resistance of the powder; but it is not necessary to be *un grand savant* for to render an account of that phenomenon. These changes of resistance proceeded from a variable state of compression of the powder which was of necessity subjected to the mechanical action exerted by temperature on the tube which contained it. I have truly no merit in explaining this simple cause which has struck all those who have handled my tubes. I will add besides, that if it had been able to escape my own notice it would certainly not have escaped that of everybody else at that time.

I believe that it would not have said much for Prof. Barrett, supposing he had been in my place, if he had hesitated a single instant to recognise the cause whose effect he had thus ascertained. This being so, is it possible for any unbiassed mind to suppose that I could not then explain the action of pressure?

To sum up, in whatever manner I reason, I cannot find the least appearance of solidity in the arguments of Prof. Barrett, and it seems to me that it is only necessary to ask my tube itself in order that it should respond for me.

HIPPOLYTE CLERAC,

Inspecteur Ingenieur des Telegraphes.

Paris, Feb. 3, 1879.

Allow me, sir, some new reflections on the subject of the pretensions of Mr. Edison mentioned in the last letter of Professor Barrett.

Even admitting that the tubes of Clerac were not furnished with resistances variable with pressure, which is contrary to the opinion of all those who have had acquaintance with these tubes, it does not therefore follow that Mr. Edison made that discovery, even for carbonaceous powders. For here is what I have myself published on this subject in the *Comptes Rendus* of the Academy of Sciences for Dec. 2, 1872, in regard to the electric resistance of carbon powders and metallic filings:—

"The resistance of the middle medium with dry powder of wood charcoal was from 1,200 to 2,000 kilometres of telegraph line, and with metallic powders or retort carbon, from 1,200 to 2,000 metres, according to the more or less brilliant state of the surface of the metal grains and their degree of closeness (tassement) round the electrodes, &c."

For the rest I have been occupied with this question at four different times since 1856.

1. In 1856 I studied it from the point of view of the imperfect contact of the metallic studs of current interrupters (see my *Exposé des Applications de l'Electricité*, 2nd Edition, Vol. I., p. 246).

2. In 1864 I studied it from the point of view of the relative insulation of the spires of an electro-magnetic helix with bare wires (see my Memoirs on this subject in the *Annales Telegraphique*, Vol. VIII., p. 211, the numbers for March-April, 1865).

3. In 1872 I studied it from the point of view of the conductivity of semi-conductors (see the *Comptes Rendus*, Dec. 2, 1872).

4. In 1874 I studied it from the point of view of the application of electrodes on ligneous bodies (see my Memoirs in the *Comptes Rendus* for July 6, 1874, Aug. 10, 1874, Sept., 1874, and May 2, 1875).

Like Professor Barrett, I concluded that the effects determined by the pressure, proceeded from a more intimate contact of the molecules of the bodies at the point of contact. The following is what I said, in fact in my note of July 6, 1874:—

"It is always the case that the conductivity is in ratio to the degree of pressure of the plates of communication. This last action evidently depends on the *greater or less intimacy of contact which is produced at the time between the two superposed surfaces.* For in substituting a drop of distilled water instead of the pressure, we immediately get, with the plate simply placed upon the table, the maximum of deviation, just as if these plates had been pressed by presses."

This question of indifferent contacts has engaged my attention during twenty years. I have even devoted a chapter to it in my *brochure* on the conductivity of semi-conductors, and Mr. Edison cannot honestly call himself the author of a discovery made when he was hardly six years of age. It is, therefore, not without a certain sentiment of regret that I see Mr. Edison, whom I was the first to herald into France, continue to sustain pretensions which cannot be sustained, and to put forward as his own an apparatus under the name of *Pressure Rheostat*, and which is only the Clerac Tube with a micrometer added. Such a course of action is unworthy of him.

Accept the expression of my best sentiments.

DU MONCEL.

HYDRO-ELECTRICITY AND HYDRO-MAGNETISM are the names given by M. C. A. Bjerknes, of Christiania, to certain attractions and repulsions observed by him between bodies in water. The bodies he experimented with were oscillating glass bells inverted in the water, and by means of tubes and an air-pump, pulses of air, causing pulsations in the water, could be sent into the bells. When the pulsations in the two bells were concordant, attraction ensued, when discordant, repulsion. A neutral or critical point was also observed in certain cases, and lateral deviation could also be produced. We do not see why this effect should be laid at the door of electricity since it appears to be quite mechanical. Mar 79

THE VOLTAIC PENCIL.—Bellet's voltaic pencil, which has been patented in England in the names of Louis Bellet and Count Hallez D'Arros, founder of *L'Electricite*, was exhibited, along with some of its work, at the Scientific Soirée given by Admiral Mouchez, at Paris, on Feb. 21. These works comprised engravings on copper, steel, and stone, executed at first hand by the spark from the pencil point, and electro-stencils or copies of documents and drawings. It is believed that the electric graver and pencil will be useful in military topography. apr 79

—A vibrating needle, actuated by clock-work, and intended as a substitute for Edison's well-known electric pen, is the subject of a recent patent.—If newspaper reports may be credited, Mr. Edison has succeeded in perfecting his electric lighting system to his satisfaction, and purposes at once to make a public display of it.—A French inventor proposes to temper and scatter the electric light by the use of wadding made of glass fibre in place of using clouded glass shades. He claims to reduce the amount of loss by absorption by at least 25 or 50 per cent.—Engravings on copper, steel, and stone, executed by what is known as Bellet's voltaic pencil or electric graver, were exhibited at a late scientific soirée given at Paris. Recent Electrical Work at the U. S. Torpedo Station, Newport.

PREMISING that comparatively little has been done at Newport for the improvement of torpedoes during the past two years, owing to the smallness of the appropriations therefor, a special correspondent of the *World* writes that one of the most important discoveries made within that time has been Lieutenant A. R. Couden's improved method of determining the internal resistance of galvanic batteries. The method hitherto practiced at the station is described by Professor Farmer as follows:

"Introduce into the circuit of a galvanic battery a convenient rheostat and a suitable fine wire galvanometer. Open and adjust the rheostat until a convenient deflection is obtained (42° 21' is liable to least error); note carefully the deflection. Next reduce the total external resistance of the circuit one half. (This presupposes that the rheostat, as opened, offers more resistance than the galvanometer.) The needle will now be deflected more than it was at the first observation. If now another adjustable rheostat be used as a shunt across the terminals of the battery, this shunt can be so adjusted that the reading of the galvanometer shall return to the same position as in the first observation. When this is the case, the resistance of the shunt is equal to the internal resistance of the battery.

Lieutenant Couden conceived the idea that if the two changes, viz.: shortening the resistance and applying the shunt, were made simultaneously, there would be at the first instance no movement of the needle, if the proper shunt were first chosen. He availed himself of the two keys used in manipulating the Wheatstone bridge to carry out the idea. The results were quite satisfactory, but the two keys being independent of each other and far apart, required two fingers to press them, and sometimes failed to operate with complete simultaneity. To remedy this Professor Farmer had made for Lieutenant Couden a key with a single finger piece, but with two independent contact closers, which admitted of such adjustment as to secure the required simultaneous closing of the two circuits when the key was depressed. The apparatus, as thus constructed, operates with entire satisfaction.

Improvements have also been made in the method of splicing the torpedo cables and leading wires now issued to ships. Mr. Farmer says that in all insulated wire now issued to ships for permanent wires, for spar leading-wires, and torpedo cables, the conductor consists of seven strands of small copper wire, and is therefore very flexible. Should it become necessary to join two pieces of cable together, it can now be done by knotting the wire by, first, a sheet bend; second, a reef knot; third, a carrick bend. The advantages over the earlier form of splicing are four-fold, viz., first, the splicing nippers and splicers in the supply-box are abolished; second, instruction to the sailor is unnecessary, and the operation is more quickly performed; third, it is the strongest way of joining two pieces of wire; fourth, the electrical properties are all that can be desired.

The modification and improvements in the electric primer are as follows: In putting in the bridge great uniformity in length and consequently in the electrical resistance is obtained; rounding up the quills so that the primers will enter the vent guns freely; a method of "choking in" the quills and securing them firmly to the wires.

The United States steamer *Trenton's* electrical apparatus is a noteworthy result of discoveries at the torpedo station. A full description of it would occupy too much space, but it may be stated that it is for two distinct purposes—firing of guns and torpedoes, and calls and automatic fire alarms. That intended for guns and torpedoes is designed to place the firing under the control of a single officer stationed at some central point, who shall be able to fire any gun when it is ready, or either or both broadsides, or as much of a broadside as may be ready.

Experiments have also been made with the telephone in order to ascertain its suitableness for communication between the bridge and the powder magazine, as well as between other parts of the ship. It has been found possible to communicate over a cir-

cuit of 22,000 ohms, having a stated capacity of eight microfarads, whence it is easy to see that it would be entirely feasible to communicate through an ocean cable between two stations that should be at least 500 miles apart. The rapidity of communication, too, is astonishing, since 145 words in 17 seconds were distinctly heard over a short circuit this is at the rate of 512 words per minute. The possibility of communicating with way stations at a distance from the direct line, and without a loop, has been satisfactorily demonstrated by Professor Farmer and his assistants.

An Electric Blowpipe.

June 79

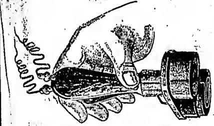
M. JAMIN, in *Comptes Rendus*, remarks that the electric arc which plays between two carbon conductors is a true current. If submitted to the influence of a neighboring current, of a solenoid, or of a magnet, it experiences an action regulated by the laws of Ampère, identical with that experienced by any metallic conductor put in its place, but as its mass is exceedingly trifling its speed is considerable. The author takes advantage of this fact to submit small quantities of matter to an intense heat. By causing the arc to be driven upon lime, magnesia or zirconia, the light is directed downwards, and its intensity increased at least threefold.

Timbreur électrique

Cet appareil, d'invention américaine, est destiné à remplacer l'instrument dont se servent les employés des postes pour annuler les timbres apposés sur les lettres. Le système en est bien simple. Un mince fil de platine, contourné de manière à former un dessin quelconque, peut être mis en communication avec une pile électrique. On ferme le circuit en pressant sur le ressort *a*, le fil de platine rougit et si l'on appuie l'instrument sur le timbre, e papier sera brûlé par le platine qui fermera ainsi une marque complétement ineffaçable.

Apr 20

Le cliché qui suit est tiré du *Monde de la Science et de l'Industrie* à qui nous l'avons emprunté.



TIMBREUR ÉLECTRIQUE. — On voit à gauche les fils destinés à amener le courant.

Nous avons bien des fois à citer des exemples dans lesquels le succès de l'audition téléphonique a été empêché par les bruits parasites résultant du passage d'un courant dans une ligne voisine.

Il y a déjà quelque temps que le problème de leur suppression occupe les électriciens.

Nous nous bornerons à faire comprendre le principe tel qu'il paraît avoir été imaginé par M. Wilson.

apr 79

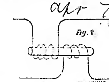


Fig. 2

... courant avec bobine de résistance.

Comme on le voit par la figure ci-contre, on enroule autour d'un morceau de fer doux le fil du téléphone et un bout du fil de ligne qui lui est parallèle pendant un nombre plus ou moins grand de milles.

Il en résulte que le courant qui se propage dans la ligne télégraphique donne naissance à deux courants, le courant d'induction dont on veut se protéger, et un courant inverse produit par l'enroulement sur le fer doux.

Ces deux courants, allant en sens inverse l'un de l'autre, tendent forcément à se détruire.

Pour qu'il y ait neutralisation parfaite, M. Wilson a imaginé de placer dans chaque circuit une bobine de résistance dont on fait varier la longueur.

MR. LATIMER CLARK has issued an address to the President and Council of the Society of Telegraph Engineers, suggesting wider scope for the Society.

MR. SCUDAMORE has gone to Beyrouth at the request of Midhat Pasha.

AN ELECTRIC BORER.—M. Gaston Planté has published his important researches on electricity and the electric discharge in an octavo volume dedicated to the Emperor of Brazil. From a copy of these very interesting studies now before us, we extract the following passage relative to the boring power of the electric spark:—"We have seen that one of the electrodes which conveys a current of a certain electromotive force on being put in contact with glass, in presence of a saline solution, acts as a graver or a diamond in cutting furrows on the surface of the glass, ploughing it even deeply. Rock-crystal can also be attacked, despite its hardness, by the same method, and if it does not yield regularly it at least bursts into pieces under the influence of the electrode, and ends by breaking up. In America black diamonds are employed in rock drilling for wells and mines. Could these expensive tools not be replaced by the action of the electric current in conditions analogous to those which have been described, and the perforation of rocks be performed by electricity? Electrodes of platinum would not be necessary, for it is not the metal of the electrode which alters, but merely the silicious matter in presence of the saline solution. Metallic points or studs conveniently distributed at the end of the drill and put in rotation would direct the electric discharge to the rock, which it would pulverise as in the case of the diamond drill. The recent advances

in the production of electricity by mechanical means would facilitate this application."

A New Departure in Electrical Education.

WE learn that Dr. Muirhead and Professor Ayrton propose receiving at their electrical laboratory, adjoining the telegraph works of Messrs. Latimer Clark and Muirhead, pupils who desire to receive a complete education as telegraph engineers, and especially those who are anxious to be trained in conducting original research in electricity and magnetism. In addition to their receiving practical instruction in the manufacture and testing of electrical apparatus and in the mathematical theory of electricity as technically applied to telegraphy, we understand that it is proposed that all the students shall be placed in charge of original experimental investigations. We need hardly refer to the difficult task of duplexing the long submarine cables in the Atlantic, Mediterranean, Red Sea and Indian Ocean, successfully accomplished by Dr. Muirhead with his "inductive resistance," or to the numerous experimental researches of Professors Ayrton and Perry, carried out in the electrical laboratory at the Imperial College of Engineering in Japan, as evidence of the thorough training students are likely to receive.—*The Electrician.*

86

Le domptage des chevaux par l'électricité. — Dans le domptage des chevaux méchants, on emploie des procédés bien différents. Certains dompteurs n'agissent que par la force, d'autres par la douceur, par l'habileté, ou par la fatigue, ou encore par l'affaiblissement résultant de la privation de nourriture, en somme par un grand nombre de moyens. La Compagnie des omnibus de Paris emploie depuis quelque temps à cet usage l'effet de l'électricité. A la dernière séance de la Société nationale d'agriculture, M. Bella a donné sur ce sujet de très intéressants détails; par l'emploi de ce procédé, des chevaux vicieux, soit cherchant à mordre, à ruer, à frapper, deviennent inoffensifs, obéissent et se laissent atteler et panser sans résistance. Il a suffi pour obtenir ce résultat de faire passer dans la bouche de l'animal un faible courant électrique à chaque tentative de résistance. Sous cette impression, la volonté du cheval semble annihilée, et celui-ci se soumet. Le courant est produit par une petite machine d'induction, du système Clarke, dont les fils communiquent avec le mors de la bride. Cette idée avait déjà été proposée à l'Exposition. Dans la section suédoise, se trouvait un appareil ayant le même but. Il se composait d'une petite boîte de 10 à 12 centimètres contenant une pile dont les fils communiquaient au mors par les rênes; en cas de résistance du cheval, le conducteur n'avait qu'à pousser un bouton pour qu'aussitôt le courant passât et que l'animal fût dompté. L'emploi de l'électricité produit plutôt une gêne, un engourdissement qu'une douleur, et est en somme beaucoup moins barbare que les procédés de domptage employés jusqu'à ce jour. (*Correspondance P. Guyot.*)

An ingenious apparatus, intended to reproduce telegraphically at a distance the pictures obtained in a camera obscura, has, says *Galignani*, recently been invented by M. Senlecq, of Ardres. The principle on which it is based is the property possessed by selenium of presenting a very variable and very sensitive electrical resistance according to the different gradations of light. 79

AN ELECTRICAL MOUNTING TABLE.

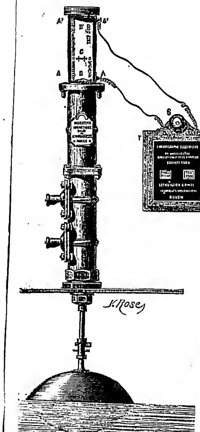
[15660].—On page 112 I notice a description of an electrical mounting table, and as I have thought some of the many readers of the MECHANIC might be interested in the subject, I will give my experience with regard to such tables, driven mechanically. About a year ago, I thought I would apply clockwork to a table I was then using, but on considering the matter, it seemed to me quite unnecessary to apply a continuous motion to it, as a slide can be ringed in a very short time, and the table must then be stopped to remove it. I therefore adopted a method which I consider simpler, and at the same time more convenient, and far less costly than the one described by Mr. Rogers, and which I will, without filling up your space with unnecessary diagrams, try to make clear to your readers.

The milled portion which is used to spin an ordinary turntable is replaced by a small cog-wheel, and in a horizontal slot in the mahogany support, in a line with this small wheel and gearing into it, is a segment, of about 1-6th of a cog-wheel, say 4in. diameter; this segment is continually pressed by a strong spring to the left-hand side, against a small indiarubber stop, and has then moved so far as to be out of gear with the small wheel, and plenty of clearance. A trigger in the form of a hook, working vertically in the mahogany,—the hook catching the lower side of the segment when pushed over—completes the arrangement. The action is as follows. The segment is pushed over and is held by the catch, the slide being in position, and brush and varnish handy. On placing the hand holding the brush on the support, the catch is released, the segment flies round, carrying the table round in the opposite direction; and clearing it, the table continues to revolve. If we could only manage to remove and replace the slides, a moderately well-balanced and weighty table would turn a sufficient time to ring, perhaps, five or six slides. But with all its advantages there is a considerable drawback to all contrivances of this kind; and that is their cost. During the years I have worked amongst scientific men, I find that nearly all our really hard workers are untroubled by a superfluity of cash. Money makes men too lazy to work, as science requires, for love alone. My aim has, therefore, been to cheapen such appliances, and still retain their efficiency. I have been so far successful as to at least satisfy myself as regards a good and simple mounting table, and I will in a few days send a sketch and description, and impose upon the kindness you so freely extend to all.

Spencer Rolfe.

87

tablet is connected with the magnetic indicator by two electric wires. At the lower part of the dial of the indicator are placed two pieces of copper, A, and upon each of these is fastened a platinum plate, B. These platinum plates are superposed at a distance of about two millimeters. When the index, C, descends, it rests on the upper piece of platinum, depresses it, and puts it in contact with the lower. An electric current is thereby established, the bell, S, rings,



ELECTRIC BOILER INDICATOR.

and, at the same time, the sign "*Low water*" appears on the tablet. Similar pieces of copper and platinum are fixed at the upper part of the dial; and, when the index reaches this limit, the bell rings, and the indication "*Too much water*" turns up on the tablet. In order to remove the warning words from the tablet, a button is pressed, which returns the indicating parts to their normal position.

THE ATLANTIC AND PACIFIC INTEROCEANIC CANAL.

To the Editor of the Scientific American:

It is now twenty-two years since I had the honor of reading before the Institution of Civil Engineers, London, a paper "On the Junction of the Atlantic and Pacific Oceans and the practicability of a Ship Canal, without Locks, by the Valley of the Atrato," and the President, Robert Stephenson, M.P., then remarked, with the kindness and urbanity that distinguished him, "the Institution was much indebted to Mr. Kelley for his highly interesting paper, which had induced the expression of valuable opinions," and concluded with the following words: "A few years longer would probably decide, whether it was feasible to make an interoceanic canal; at any rate it could not fail to be remembered that Mr. Kelley had produced more intelligible information upon the subject, than had hitherto been given to the world." In view of those opinions of a deeply lamented and great man, I hope I shall not be deemed presuming too much on them in venturing to call the attention of your readers to the advantages of constructing a ship canal *via* the San Blas route, surveyed under my direction in 1861, by Mr. A. McDougal, chief engineer. I offer them to you in hopes that their publication may suggest to the English people that a short and safe route for a ship canal through the American Isthmus can be secured for European commerce to Australia, New Zealand, and all the trading ports in the North and South Pacific Ocean, and which may be preserved strictly neutral, under the joint protection of England and the United States—the two great English speaking nations, enjoying the same religion, reading the same literature, maintaining the same liberty, and practicing the same laws; therefore they ought to go hand in hand in the execution of the work.

Great projects seldom die. When once any considerable number of men become convinced of the importance and utility of an enterprise, however vast, it is considered and discussed from year to year, from generation to generation, and from age to age, until the time, the facilities for execution, and the men are collected together, and the work is accomplished. The Suez Canal is a striking example. From the earliest days of modern commerce a strong desire for its

REMOVING WIRE AND IRON FROM WHEAT BY MAGNETS.

The removal of wire from the miller's wheat seems su[dd]enly to have expanded into one of the subjects most i[m]portant to the miller. The bits of wire that are found [in] the thrashed wheat are a nuisance that can be said to ha[ve] had its origin about two years ago, as before that time t[he] wire self binders were but comparatively little used. La[st] season, however, at least 25,000 wire binders were employ[ed] by the farmers, principally in the Northwest, and the manu[fa]cturers of agricultural machinery are now preparing [to] sell as many more during the coming season. One Clev[e]land firm now has on its books orders for over twelve mil[lion] pounds of the steel wire used by the self binders. Th[is] certainly shows something of the magnitude of the busine[ss] which is expected to be done in wire binders this seaso[n]. It certainly cannot be denied that the self binders are a va[st] improvement over the old method of harvesting, and, [...]

China, and excellent silk may be made by dexterous management with a good hand-reel.

"Raw silk is classified into organzine, tram, and floss. Organzine is considerably twisted and is the choicest. Tram is made from inferior cocoons and is but slightly twisted. Floss is made of the loose silk, carded and spun like cotton or wool.

"The thread of silk as it unwinds from the cocoon is valueless for manufacturing purposes, several of them combined going to make the staple of commerce. The persons employed in unwinding silk are mostly women, one standing or sitting before each basin, of which she has entire charge. The basin is made of copper, and, in the large establishments, the water in each basin is heated by steam, at the control of the operator. The cocoons are plunged into the water, when it is near the boiling point, and moved about so that the gum which fastens the threads becomes uniformly and thoroughly softened. They are then beaten with a small birchen broom, having the tips split, so that the loose threads readily fasten to them. After beating a short time, the operator gets all the cocoons fastened, and, taking the bundle of threads, shakes the cocoons till each hangs but by a single one. She now takes up five or more threads (*brins*), according to the quality of silk wanted, unites them, and introduces the combined staple or strand (*fil*) into a little glass eye on one side of the basin. She then forms a second similar strand and introduces it into a second eye on the other side. The strands are then brought together, twisted several times, separated above the twist, and introduced into two other glass eyes or ringlets, through which they are led, one to each end of the reel or *tambour*, which is kept revolving in a steady, rapid manner, and to which is also given a certain back-and-forth side motion. The great object in reeling is to get the threads uniform, rounded, well joined, properly freed from moisture, and so crossed on the reel that they will not stick or glaze, as it is termed. These objects are attained by the twisting and the to-and-fro lateral movement of the reel, as also by properly regulating the distance between reel and basin. The uniformity of the thread depends on the skill of the operator, who must supply a new thread as soon as one begins to give out. This is called nourishing the silk, and is done by dexterously casting, with the thumb, the new thread upon the combined strand, to which it immediately adheres. In this she must use much judgment, for the silk of a cocoon gradually gets lighter and finer as it approaches the end, and the uniformity of strand does not entirely depend on the uniformity in number of the individual threads forming it. Whenever the silk rises in locks the temperature of the water is known to be too hot, and when it unwinds with difficulty the temperature is, on the contrary, too low. The operator is supplied with a skimmer with which to remove all chrysalides and refuse silk; also, with a basin of cold water in which to cool her fingers, which are being constantly dipped in the ho[t water]. This constitutes the whole operation of unwinding, [but] before the skeins, as they come from the reel, are ready for the manufacturer they must undergo still further manipulation. The staple is first passed through a cleanser, consisting of a clasp lined with cloth, which catches any loose silk or other matter that may be adhering to it. It is then further cleansed and purged by being passed through four similar cleansers (*purgeurs*), then twisted about 500 times to the yard, then doubled and again twisted about 400 times to the yard. It is finally run on to reels about 1½ feet in diameter, and taken off and twisted in a peculiar knot or hank. Through all these operations the oscillating to-and-fro lateral motion is kept up, so as to produce the diagonal crossing of the strands, and it will be readily understood that each [...] of the strands

REMOVING WIRE AND IRON FROM WHEAT BY MAGNETS.

such, are likely to be sooner or later adopted by the farmers of the country.

The cost of the wire for binding the wheat ranges from fourteen to forty cents per acre cut, and one machine will cut about sixteen acres of wheat in one day. We can readily see the advantages, to the farmer, of using such a machine, but to the miller, the result of the introduction of the self binders has been injurious in many instances. Small bits of wire find their way through the thrashing machine into the wheat, and, concealed by their specific gravity, into the miller's garners. It may appear strange that these small steel particles should pass through all the cleaning machinery of the mill to the burrs, through these into the meal and bolts, and sometimes through the bolting cloth into the flour and biscuit.

The pieces of wire range in size from a pin head to an inch in length. They are flattened by passing through the burrs, and their edges, when examined through a microscope, are found to be serrated, and, therefore, admirably suited for cutting the bolting cloth to pieces. We have before this enlarged on the evils which such sharp instruments produce, and any further comment or citation is unneces-

Fig. 2 shows the bend or crimp made before the wire is commenced to be cut, and which prevents the spring of the bundle pulling it out when the cut is finished, or the wire finally parted.

Fig. 3 shows the crimp (which is made before the cut) intensified, when the cut is finished, into a sharp V, making a positive hold, so that the wire cannot be pulled out, unless the operator relaxes his grip, or chooses to let it pass into the thrasher.

If farmers could be persuaded to use the best possible means for removing the wire, united with some degree of care, but little wire would find its way into the mill. Nevertheless, even with the greatest care, the wire will get there, especially if the bands have rusted from exposure. The wheat cleaning machinery will remove many of the bits of wire, and the efficiency of the separators may be increased by making "riffles" straight up and down, on the sieves, in the same manner as employed for taking out gold. But, [so] far, the most perfect instrumentality that has been employ[ed] is the magnet. We have, in former articles, explained ho[w] these magnets are used. Their application is simple, [and] they may be placed in any part of the mill or on any [...]

Rock Drilling by Electricity.

In a recently published work of M. Gaston Planté, "Recherches sur l'Electricité," noticed in one of our French exchanges, the author mentions a new application of electricity which had not been hitherto published by him, and which is of considerable interest.

After describing the process of engraving on glass by electricity, that he made known in 1877, and the account of which has been so widely copied by scientific papers, M. Planté goes on to say: "We have seen that one of the electrodes conducting an electrical current of a certain tension being brought in contact with glass, in the presence of a saline solution, it acts like a graver or diamond by tracing grooves in the surface of the glass, and even digs into it quite deeply. In spite of its great hardness, rock crystal can also be attacked by the same method; and, if not engraved regularly, it at least cracks into small fragments, and is finally disintegrated." In view of this, M. Planté suggests that the electric current, under conditions analogous to those above described, might be substituted for diamonds in the operation of drilling rocks. He states that electrodes of platinum would not be necessary, for here it is not the metal of the electrode that is affected, but the silicious matter in contact with a saline solution. Metallic points or projections suitably located at the extremity of the drill, isolated on a part of its length and actuated by a rotary movement, would lead the electric current to the surface of the rock to be pulverized, and would thus replace those numerous and expensive diamonds which are set in the head of the drills employed in the present system of rock boring.

L'électricité appliquée aux pompes à incendie

May 16 1880

L'*American Register* nous fait connaître qu'aux États-Unis [on a] trouvé le moyen d'appliquer l'électricité aux appareils des pompes à incendie. Un fil métallique parcourt le tuyau de la pompe dans l'intérieur de la toile ou du caoutchouc, et sert de conducteur à l'électricité produite par une roue à volant de la pompe à vapeur. A l'extrémité du tuyau, à côté de la lance, est un système permettant au pompier, sur le lieu du sinistre, qui est souvent à une assez grande distance de la pompe, de communiquer avec celle-ci et de faire cesser, ralentir ou activer le jeu; le signal se donne au moyen d'un timbre mû par l'électricité et frappant sur un tam-tam suspendu à la machine.

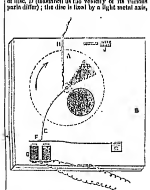
[36110.]—Electric Shutter for Camera.—I have made such a shutter not only to work in an ordinary camera, but adapted it to my lilu. reflector, and used it in conjunction with my chronometer to take solar photographs, thus using the same current to take photos and time. The shutter may be thus described: the centre of a revolving disc of thin metal, A, is placed at the side of lens (say 1in.), and is inclosed in a light thin box of wood, B; this box fixes on the lens or eye-piece, C; the opening through which the rays of

light pass is cut out of both sides of this box in which disc revolves. Cut an angular opening out of disc, D (inasmuch as the velocity of its various parts differ); the disc is fixed by a light metal axis,



one end of which is bent at right angles to axis outside front side of box, E, and therefore moves in a plane parallel to face of box. The end of this arm can be fixed under a very small catch, soldered on the spring, F; this is acted upon by a small electro-magnet, G. The disc is caused to revolve by a slender piece of indiarubber elastic, H, running over a little pulley or grooved wheel fixed to axis of disc; this may be tightened to increase the rapidity of revolution. J is a buffer to check lever of rubber. Carry a small portable battery cell in pocket, stand immediately behind camera, and make contact when necessary.—H. A. Severn, Herne-hill, S.E.

Dr. Coffin recently exhibited before the Physical Society a Trouvé polyscope, which consists of a small, hand, incandescent platinum wire electric light, designed for illuminating the more inaccessible cavities of the body in surgical examinations. The current is supplied by a Planté secondary battery, and the light is half inclosed in a small silver reflector fitted with a convenient handle. The apparatus is portable. Dr. Coffin found that it was open to several objections which he has remedied. First, the heat generated made the lamp so hot that it could not be held to the body for more than a very short time. He overcame this by making the reflector of double silver plates, and circulating water between by means of india-rubber pipes and a bulb which can be worked by the patient himself, thus serving to distract his attention from the operation. Secondly, the secondary battery exhausts itself in twenty minutes, and the light therefore goes out, while from twelve to twenty-four hours are required to recharge it. Dr. Coffin has superseded it by a Leclanché battery of eight elements, made by Messrs. Coxeter and Sons, in which the carbon pole is replaced by a copper plate faced with platinum, and no porous diaphragm is employed. This gives a constant light for several hours. June 79

Le labourage à l'électricité. — L'application de l'électricité, comme force motrice, appartient désormais à la science et à l'industrie. Elle a été affirmée, le jeudi 22 mai, par la remarquable expérience faite à Sermaize en présence d'une délégation de l'Institut, une Commission de la Société nationale d'agriculture de France et de la Société des agriculteurs de France. June 79

Une foule de 1200 à 1500 étrangers était accourue des villes et bourgades voisines.

Les inventeurs ne se servent pas de piles, mais emploient les machines Gramme, qui fonctionnent déjà pour la production de la lumière. Le courant électrique, produit à l'usine, est transmis, au moyen de fils de cuivre, à la locomobile électrique faisant mouvoir la charrue. Les fils peuvent être considérés comme une longue courroie de transmission, et l'ensemble comme un immense télégraphe, transportant une force énorme, au lieu d'une force insignifiante. Avec un moteur unique, on peut transmettre la force à plusieurs kilomètres; la déperdition de force est moindre que par tous les autres procédés employés, et surtout que celle d'une locomobile à vapeur fonctionnant à l'air pour le labourage ou le battage des grains.

On peut utiliser comme moteur principal les cours d'eau, les moulins à vent, en un mot toutes les forces naturelles ou autres. Dans une ville, dans un village, il suffira d'établir une puissante machine électrique près de la roue d'un moulin, et chaque industriel pourra, au moyen de fils communiquant de son usine au moteur, trouver la force nécessaire pour son travail. Chaque cultivateur pourra, par le même système, faire marcher sa batterie, en payant un faible tribut au propriétaire du moteur principal. Sur les canaux, l'eau qui sort des écluses, au moment du passage des bateaux, peut, au moyen d'un petit moteur hydraulique qui se trouverait en dehors de l'écluse, donner le mouvement à une machine électrique; celle-ci, à son tour, communiquerait l'impulsion à une locomobile électrique, et cette dernière, se mouvant d'elle-même, s'avancerait seul sur la berge du canal, et ferait facilement le halage des bateaux. Les travaux mécaniques des carrières, mines, souterrains, seront désormais possibles sans l'emploi de la vapeur et avec une dépense très minime.

PRESSE.

An Electrical Rock-Drill.—The electric currents of high tension, which M. Planté has been studying for some years past, give many curious and suggestive effects. One of their effects is that of electric engraving on glass and on rock crystal. M. Planté had the idea of utilising this force in boring operations. In America and elsewhere, it is known, hard rocks are often attacked by means of diamonds, the price of which is, of course, high, and which are gradually lost by being detached through the violence of the action, from the pieces to which they have been fixed. "Might not these diamonds be replaced," M. Planté asks, "by the action of the electric currents referred to, and the rocks be bored by electricity?" He points out that electrodes of platinum would not be necessary; for it is not the metal of the electrode that is altered, but the silicious matter, in presence of the saline solution. Metallic points or projections suitably placed at the extremity of the drill rod, insulated in a portion of its length, and animated by a rotatory movement, would bring the electric current to the surface of the rock to be pulverised, and would thus replace the numerous diamonds set in the head of drills employed in the present system of rock-boring. The progress recently accomplished in production of electricity by mechanical methods might facilitate this application. June 79

An Automatic Electric Bell.—An ingenious and simple apparatus for making a bell ring at any predetermined hour of the day, is described in a recent number of *L'Electricite*. It comprises a lens by means of which the solar rays are concentrated and directed on a metallic strip, which is susceptible of very rapid and great dilatation. The result of the dilatation is electric contact, giving passage to a battery current which rings the bell. Although the sun may be covered by clouds, its calorific power is never diminished so much as not to dilate the strip. Mining Herald Dec 20 1879

The Electric Hose.—A new thing in fire apparatus is the electric hose. A wire runs along in the cotton or rubber part of the hose, continuing the connection as each section is attached, and over this passes electricity, generated by one of the fly wheels of the engine. Connected with the nozzle is a little contrivance by which the engineer can be directed, although squares distant from the man who is playing water on a fire, to turn her on, cut her off, stop, go ahead, or any thing else that may be agreed upon by a signal which is struck on a gong attached to the engine.

An Electric Sentinel.

Persons who have occasion to cross the Providence railroad on Washington street, at Forest Hill, Boston, are frequently surprised to hear a heavy gong continually ringing on a danger-signal post close by, while no approaching train is seen or heard; but from three to five minutes after the alarm first sounds a train dashes around the curve and speeds along, while, as it leaves the crossing, the gong ceases to ring. This crossing signal is part of the system of the Union Electric Signal Company. It is known as the Union Electric Signal, and is exceedingly simple. By this system electricity is carried to the rails, holes being drilled in

To the Editor of The Telegraphic Journal.

ELECTRO-SOLAR ALARM.

Sir,—I read in your interesting Journal that an electro-solar alarm *has been invented*, by which a bell is rung when the sun passes the meridian. Already certain French journals had reported that so-called invention with a great fuss, and I did not think it worth while to claim it, because of its small importance; but since the Telegraphic Journal, which is a serious organ, seems to attach some interest to it, I feel myself called upon to inform you *that this invention is only the germ of an apparatus which I designed and constructed in 1856 under the name of the Electro-solar Regulator.* You will find a long description of it in volume ii., page 255, of the second edition of my work on the Applications of Electricity, published in 1856. That apparatus aimed not only at indicating the moment of passage of the sun across the meridian, but also to adjust to the true meridian the hands of a clock, and thereby to indicate the true time. I described two plans for this purpose, but the second gave the best results. My descriptions are accompanied by very exact figures, which are engraved in plate vii. of the said volume.

This description is also reproduced in the fourth volume of my last edition, page 78. The idea has been taken up two years later by M. Régnard, and in 1868 by the Abbé Candido da Lecco.

I beg you to accept the assurance of my best sentiments,

DU MONCEL.

Nature Mch. 15, 1881.

Nature Mch 15 1881

EDINBURGH

Royal Society, February 21.—Prof. Fleeming Jenkin in the chair.—Sir William Thomson communicated a paper by Mr. Witkowski on the effect of strain on electric conductivity. A cylindrical brass tube, with a magnet and attached mirror suspended horizontally in the centre at right angles to the axis, was traversed from end to end by an electric current. In its original unstrained isotropic condition the cylinder so conducted the current that the inclosed magnet was unaffected. A couple was then applied in a plane at right angles to the axis, so as to distort the metal tube by a definite twist, thus rendering it æolotropic as regards its electrical conductivity, and giving to the current a spiral set, which was evidenced by the deflection of the suspended magnet. The lines of flow set spirally round in a direction contrary to that of the applied couple—a result in complete accordance with the theory of twists, which requires a lengthening (and therefore an increase of resistance) along spiral lines that set round with the couple and a simultaneous compression (and corresponding decrease of resistance) along lines at right angles to these. Quantitative results were obtained by balancing the electro-magnetic action of the current in the strained tube by means of an external circular movable conductor traversed by a steady current.—Sir William Thomson described certain experiments which he had lately made on the effect of moistening the opposing surfaces in a Volta condenser, and of substituting a water-arc for a metallic arc in the determining contact. The main features of the paper were, the non-existence of any measurable difference of potential when contact was made by means of a drop of clean water between opposed polished surfaces of zinc and copper, the effect of oxidising the surfaces in the pure metallic contact experiment, and the exact similarity in the action of dry polished zinc and wet oxidised zinc when opposed to dry copper and brought into contact by a metallic arc. Sir William also described the "vortex sponge." A vortex column spinning at the heart of a mass of fluid revolving irrotationally inside an imperfectly elastic cylindrical case forms a system in a position of maximum energy; and any slight disturbance from the truly circular rotation of the vortex core results in a gradual drawing off of energy, in virtue of the imperfectly elastic character of the bounding material, until the system assumes its position of minimum energy with the rotationally-revolving fluid on the immediate inner surface of the inclosing case and altogether surrounding the irrotational fluid, which is now in a state of quiescence. The intermediate stages between these first and last conditions are what Sir William Thomson characterises by the name of vortex sponge.—Mr. T. Muir presented a paper on continuants, to which special form of determinant he could, by suitable transformations, reduce any given determinant of ordinary type, and so was able to express a determinant as a continued fraction.—Prof. Chrystal added a note on this paper showing how in the most general case n equations between n unknown quantities can be made to yield by suitable elimination n other equations, in no one of which more than three terms appear, so that a continuant form of determinant is got which bears a simple relation to the determinant formed by the coefficients of the original equations.

La Science pour tous

PHYSIQUE

April 1880

L'électricité et la végétation sylvestre

Au début du siècle, que savions-nous de l'électricité? Aujourd'hui la science commence à entrevoir les puissants effets de cette force à laquelle rien ne résiste. Parmi les étonnantes productions du fluide électrique, citons seulement pour mémoire: la télégraphie, la dorure et l'argenture, le paratonnerre, etc. Avec son aide, on a décomposé les corps réfractaires à la chaleur ainsi qu'à tous les agents chimiques; plusieurs maladies ont été soignées avec succès; on a tenté le chauffage électrique, et il y a lieu de croire que les grandes villes seront bientôt éclairées par cet agent destiné à transformer le monde.

Nul n'ignore que la plupart des phénomènes naturels ne soient accompagnés d'une production de force électrique. Des végétaux et des corps organiques en général viennent-ils à se décomposer; l'évaporation de l'eau, une combustion quelconque, la rouille du fer, se produisent-elles? le fluide impondérable est là. L'atmosphère, fût-elle pure et sans nuages, est toujours plus ou moins chargée d'électricité.

Le temps est lourd, disons-nous quelquefois; c'est qu'un agent invisible agit sur nos nerfs, qu'il excite le plus souvent. L'électricité, plus abondante à mesure qu'on s'élève davantage dans l'air atmosphérique, fait défaut dans les maisons; sous les arbres et, en général, partout où règne un abri, un ombrage.

Ces phénomènes naturels sont connus depuis longtemps déjà, et cependant l'influence pernicieuse du couvert des arbres sur la végétation sous-jacente était jadis attribuée au défaut de lumière.

Tout récemment, des expériences faites par M. Grandeau, notre éminent professeur à l'Ecole Forestière, ont démontré péremptoirement que, sans électricité, les végétaux sont impuissants à assimiler les principes carbonifères de l'air atmosphérique.

Sous une cage en treillis de fer, posée sur un terrain parfaitement découvert où le soleil dardait ses rayons, il plaça des graines de très-bonne qualité et récoltées par lui. D'autres, de même espèce et de provenance aussi certaine, avaient été semées tout près de là dans un sol également bien préparé. Au bout de quelques jours, celles-ci sortirent de terre et se développèrent fort bien. Les autres, qu'on avait placées sous la cage, ne germèrent point d'abord; mais, dès que la cage fut enlevée, les cotylédones se manifestèrent, la gemmule apparut et le petit végétal se montra. On replaça bientôt cette sorte d'écran et la croissance fut suspendue.

Au cours de l'expérience, les graines étaient arrosées chaque jour et les rayons solaires passaient aisément au travers des larges mailles de la cage en fer. Ni l'air, ni l'eau, ni la lumière ne faisaient défaut à la jeune plante. Que lui manquait-il donc pour se développer? La force électrique sans doute.

Dans la forêt, comme en rase campagne, l'arbre joue le même rôle que la cage de fer sur les graines qu'on a semées à l'ombre de ses rameaux.

Avant cette belle découverte, on disait, pour expliquer l'action pernicieuse des arbres sur la végétation sous-jacente, que le végétal dominé ne recevait pas directement l'action des eaux pluviales et qu'il ne pouvait assimiler les principes carbonifères de l'air atmosphérique sans le secours de la lumière blanche. Cette explication est réduite à néant par l'ingénieuse expérience de notre honoré maître qui donna à ses graines tous les éléments nécessaires, sauf l'électricité.

Pour se rendre un compte exact de l'importance du rôle que joue la force électrique sur l'assimilation des végétaux, nous ajouterons que la production moyenne de nos forêts est annuellement de 6.000 mètres cubes de bois pesant 3.000 k., et en outre du même poids de feuilles et de graines.

...américaine.

Le lendemain du jour où M. de Lesseps entretenait le Comité des travaux publics du Congrès de ses projets de percement du canal de Panama, M. le capitaine J.-B. Eads, de Saint-Louis, a donné connaissance à ce même Comité des facilités et des avantages que présenterait, selon lui, l'établissement d'une voie ferrée pour le transport des [illegible] la substance des explications produites par l'ingénieur américain; Disons que M. Eads n'est pas le premier venu, et qu'il vient de conduire avec beaucoup d'habileté des travaux très-importants à l'embouchure du Mississipi. Il va sans dire que, comme tous les inventeurs ou promoteurs d'une idée nouvelle, il a la plus grande confiance

AN ELECTRICAL WATER LEVEL INDICATOR.

Amongst the objects exhibited at the recent *soirée* of the Institute of Civil Engineers, held at South Kensington, the Electrical Water Level Indicator, belonging to the Nottingham Waterworks Company, and designed and constructed in the engineering department of the Postal Telegraphs, excited much interest. The apparatus exhibited consisted of a "Transmitter" and a "Receiver," the latter being in connection with a transmitter fixed at one of the reservoirs of the Company referred to, at Nottingham. During the course of the evening the visitors had thus the opportunity of seeing the actual working of the apparatus, and of observing the changes in the level of the water in the reservoir at Nottingham. Apart from the ingenuity of the invention, the apparatus exhibited was a masterpiece of constructive finish, and did extreme credit to the Postal Telegraph mechanicians. The principal part of the apparatus is the "transmitter," by means of which, on the rising of the float attached to it, a *momentary* contact is made, which causes a positive current to be sent to line at every inch of rise, and a momentary negative current at every inch of fall of the float. The importance of arranging the apparatus to make *momentary* contacts only is evident, otherwise, from the slow rise and fall of the water level, the series of currents would be continued ones which would soon exhaust the battery.

June 79

93

The method by which the object in view is obtained is shown by fig. 1, which represents the arrangement of the "transmitter." *f* is a small metal disc, having a quarter of its circumference faced with a projection of platinum *b*; this projecting piece makes contact, when the disc is turned, with either the spring *d'* or *d"*, the ends of the latter being faced with platinum to insure good contact being made.

The disc *f* is fixed to an axis, to which is also attached the weight w; on the axis is a pinion, into which the wheel A gears.

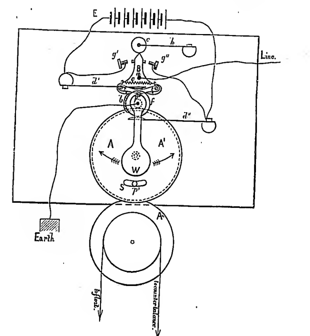

Fig. 1.

Behind wheel A is a second wheel A' (shown by the dotted line); this wheel has a pin *p'*, which works in the slot s cut in the front wheel A; the length of this slot is such that if we suppose the pin to be at one end of the slot, and the wheel A' to be held in that position, then a rotatory movement of the wheel A, sufficient to move the other end of the slot up to the pin, will cause the disc *f* and the weight w connected to it to make a complete revolution, that is to say, the weight w will have been turned in the direction of one or other of the arrows according as A is turned, in one direction or the other, and when it has made a complete revolution, together with the disc *f*, then the latter will have made contact with both the springs *d'* and *d"* in succession.

Fixed to the face of the disc *f* is a pin *p*. This pin, when the apparatus is in the position shown in the figure, lies between two pawls *t t*, attached to the triangular piece B, which rocks on a centre *a*. The pawls are maintained in the position shown, relative to the piece B, by a small spiral spring *e*, which draws them down against small stop pins fixed on B.

The whole rocking piece can be thrown over against either of the contact screws *g'* or *g"*, and

94

when against either of them will be held firmly there by the little wheel c, which presses, by means of a spring h, against either one side or the other of the pointed top of n.

The wheel A" which gears into A' is connected to the float by means of a chain, and the whole arrangement of the gearing is such that an inch rise of the float can turn the disc f through a complete revolution.

The electrical connections are those shown, the line being connected to the rocking piece n, which is insulated from the rest of the apparatus.

To understand the working of the arrangement, let us suppose that all the parts of the apparatus stand in the position shown, when the float stands at an exact inch mark. Let us suppose the water commences *rising*; for the first half inch of rise then, the wheel A' will have been turned so as to bring the pin p' to the left hand end of the slot; as the wheel A' then continues to rotate it now turns the wheel A and rotates the disc f, and also moves the weight W, in the direction of the right hand arrow. The rotation of the disc causes the pin p to push against

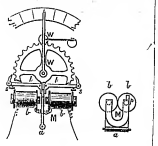

FIG. 2.

the left hand pawl of the rocking piece n, and to move the latter over towards the contact screw g". After a certain angular movement of n has taken place, the action of the spring c carries it completely over to g", and in this position the pin p clears the left hand pawl. Supposing, now, the rotation to be continued so that the lever of the weight W is at right angles to the position shown, then the platinum projection b will be making contact with the spring d"; but this will not cause any current to pass out to line, since in this position both line and earth (which is connected to the frame of the apparatus) are both connected to one pole of the battery, whilst the other pole of the latter is free. On continuing the rotation, however, the weight W arrives at the vertical position, which completes the inch movement of the float, and then topples over to the left making contact in its fall, by means of b, with the spring d'; at the moment when this takes place zinc is to earth through the spring d' and the projection b, and copper is to line through g" and n, consequently a positive current is sent to line.

When the weight has completed its descent the whole arrangement resumes the position shown.

The pin p, it may be observed, in passing the right hand pawl, when the weight is falling, merely lifts it up and passes under it without affecting the position of n; in fact, as long as the rotation of f takes place in the direction just indicated, n will remain over against g".

Inasmuch as f is geared, through the medium of the pinion, direct on to A, the quick fall of the weight will cause A to rotate through a corresponding angle: this the slot s allows A to do without affecting A'.

If the float falls, all the motions become reversed, viz.: the rocking piece n becomes thrown over to g', and a negative signal is sent when b makes contact with d', for then zinc is to line through g', and copper to earth through d".

It will be evident that the whole arrangement is such that a signal cannot possibly be transmitted unless the weight makes a complete revolution, and then it can only be a momentary signal.

The receiving portion of the apparatus does not possess any particularly novel points. It is represented by fig. 2 (drawn to a smaller scale than the transmitter); M is a horse-shoe permanent magnet, fixed on an axis a, so that its poles can move backwards and forwards between the poles of two ordinary electro-magnets b b, whose wires are joined together in one circuit. A projecting piece p, of the horse-shoe magnet, lies between the bent arms of the levers l l. These levers rest normally against the stop screws s s. When a positive current passes through the electro-magnets, the permanent horse-shoe magnet is moved, say to the left, thereby moving the left-hand lever, the pawl at the end of which moves the toothed wheel W one tooth forward, representing one inch of movement of the float. Similarly a negative current moves the horse-shoe magnet in the reverse direction, thereby actuating the right-hand lever, and moving the wheel in the reverse direction.

The levers l l are so arranged that, when in their normal position, the pawls attached to them stand clear of the teeth of the wheel W. The little wheel w at the end of a spring falls between the teeth of the wheel W and keeps it steady.

Perforating Glass by Electricity.

PROF. WALTENHOFEN, of Prague, has recently described the following experiments:—A thin glass plate, having on it a small drop of stearine, is introduced into the spark-path of an electric machine. It is perforated at the part where the drop is, and more easily so when the drop-side is turned to the positive electrode. A glass plate, hung bifilarly between the electrodes of a Holtz machine, is driven by the discharge towards the negative electrode, and more strongly, if the side turned towards the positive electrode be partly covered with stearine. Prof. Waltenhofen considers that the rapidly moving air molecules in the spark-path are ruled by a component of velocity directed from the positive to the negative electrode.

Nature July 3 '79

the former.

A VERY ingenious application of electricity to the purposes of navigation has recently been effected by Mr. Henry A. Severn, of Herne Hill, who has succeeded in producing a mariner's compass which enables the captain or officer in charge to hear, by the ringing of a bell, when the vessel is out of the ordered course. The whole of the apparatus is contained in a small box which is easily carried about, and is intended, as a rule, to be placed in the captain's cabin. Over the card are two index hands, which can be adjusted to any angle allowing of greater or less deviation in steering to either the port or starboard side. Assuming the captain, on quitting the deck, to have given instructions to steer the ship on a certain course, he sets the index hands to a certain angle, allowing the steersman a given latitude for deviation either to port or starboard of that course. Should the ship be steered off her course beyond the limit allowed on either side an electric alarm-bell rings instantaneously, and, moreover, continues ringing until the right course is resumed. The metal point on which the card is hung is insulated from the compass bowl, and to it is attached a wire from one pole of a small battery. About an inch above the card, placed parallel to its surface and attached to its metal centre (which is insulated from the needle) is an arm of metal reaching nearly to the edge of the card. This arm is, therefore, in metallic communication with the wire from the battery already referred to. The glass lid of the compass has a short brass rod working within a tube passing through it. These are severally attached to two brass milled heads above the glass lid and to the two movable index-hands beneath the glass. These are in metallic contact with the brass-work of the compass, and this with the other pole of the battery. Beneath the outer extremities of the index-hands are suspended two pieces of platinum wire about three-quarters of an inch long. These hands can, by means of the two milled heads, be moved round to any position over any point of the card. Hence they admit of being placed on either side and equally distant or otherwise from the end of the metal arm on the card. It will thus be seen that whenever the platinum wires come into contact with the metal arm on the card the circuit is completed. The electric bell being placed in the circuit sounds whenever such contact takes place. Two bells of different tone can be used, and thus the instrument will indicate to the captain whether the deviation in steering is to port or starboard.

Manufacturer & Builder

Rock Drilling by Electricity.

July 79

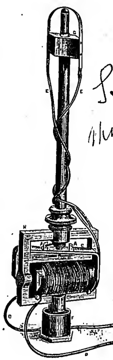
In a recently published work of M. Gaston Planté—"Récherches sur l'Electricité"—the author mentions a new application of electricity which had not hitherto been published by him, and which is of considerable interest.

After describing the process of engraving on glass by electricity, that he made known in 1877, he goes on to say: "We have seen that one of the electrodes conducting an electrical current of a certain tension being brought in contact with glass, in the presence of a saline solution, it acts like a graver or diamond by tracing grooves in the surface of the glass, and even digs into it quite deeply. In spite of its great hardness, rock crystal can also be attacked by the same method; and, if not engraved regularly, it at least cracks into small fragments, and is finally disintegrated."

In view of this, M. Planté suggests that the electric current, under conditions analogous to the above described, might be substituted for diamonds in the operation of drilling rocks. He states that electrodes of platinum would not be necessary, for here it is not the metal of the electrode that is affected, but the silicious matter in contact with a saline solution. Metallic points or projections suitably located at the extremity of the drill, isolated on a part of its length, and actuated by a rotary movement, would lead the electric current to the surface of the rock to be pulverized, and would thus replace those numerous and expensive diamonds which are set in the heads of the drills employed in the present system of rock boring.

AUTOMATIC GAS LIGHTING.

A new plan for lighting and extinguishing the street lamps by electricity has lately been tested by one of the London gas companies with results which point to a still more extensive trial. The system is one in which electric currents are made to turn the gas on, light it, and subsequently turn it off. Although three operations are thus involved the arrangement is remarkably simple. A single wire may be carried along a line of lamps and then connected with the earth, or the wire may be carried around through a circuit of lamps, so as to terminate at the station from which it started. At this station there would be a magneto-electric apparatus for generating the required currents, and one operator at this point would be able to command a number of circuits, each comprising any number of lamps up to 300 or more.



FOX'S GAS LIGHTER.

S. A. Mar 75

The experiments alluded to were made on the premises of the company, and have been published by *The Engineer*. A single line of wire, about half a mile long, was conveyed by a zigzag course along a series of twenty-three lamps. The wire was chiefly an aërial line, suspended to the lamp posts and attached to various intervening structures. It was insulated only at those points where it would otherwise come in contact with some conducting substance. The mechanism applied to each lamp, in addition to the wires, is contained in a small metallic box of circular form, so arranged as not to obstruct the light.

The accompanying engraving shows the mechanical arrangement. The socket, F, is screwed on the top of the gas pipe, and the frame, H, is made hollow for the purpose of allowing the gas to flow up to the nipple at the summit. The gas is turned on or off by means of a valve or stop cock, the lever of which is shown caught by one of the studs, A. The two studs, A A, are borne on the upper part of the permanent horseshoe magnet, C, the latter being supported on the point of a fine pivot working in a cross piece in the frame, H. This permanent magnet is capable of a reciprocating motion horizontally, and supposing its position in the drawing to be reversed, the other stud, A, would carry the pin or lever back through a short space. This shifting of the lever one way or the other serves to turn the gas either on or off, as may be desired. The movement of the magnet is effected by a change in the polarity of an electro-magnet consisting of a soft iron wire in a coil at B. According as the current is sent forward or backward through the coil, so the polarity of the core is altered and the permanent magnet is turned on its pivot. The electric current is conveyed from the magneto-electric machine at the station by the wire, D D, which connects all the lamps. Supposing the current to be sent in such a direction as to turn the gas on, the next operation consists in transmitting along the wire, D D, a powerful discharge obtained from a condenser raised to an electro-motive power of several thousand volts or units by means of a Ruhmkorff coil. Around the primary coil at B is wound a secondary coil of fine wire and of much greater length. The discharge from the condenser has the effect of producing a secondary current along the wire, E E, thereby developing a small spark just over the burner. The discharge which passes along the primary wire has the same effect simultaneously on the secondary wire in all the lamps of the circuit, so that the gas being previously turned on in the manner described, the whole of the lamps are lit. If the first and last lamps of the circuit are in sight of the station the continuity of the circuit will be proved by the lighting of these two lamps. When it is required to extinguish the lights a reverse current is sent through the primary wire, causing the permanent magnet to turn and the gas to be shut off, as described above.

Sc. Am. Aug 24 1879

SPAR TORPEDO VESSEL ACHERON.

About eighteen months ago the government of Sydney, Australia, voted £8,000 for the construction of two torpedo launches, and their design and supervision of construction were intrusted to Mr. Norman Selfe, of Sydney. As nothing over ten knots had ever been realized in launches there up to that time, Mr. Selfe sought for information in our own pages and those of our contemporaries; but editors are not at liberty to publish all they know concerning such craft for obvious reasons, so Mr. Selfe had to rely on his own resources. He had to begin at the beginning, and work the whole thing out. Since the boats have been in hand he has learnt a few particulars, but the original design has not been departed from in the slightest degree. One vessel is launched, and on a trial in a very heavy sea realized over fifteen knots; but Mr. Selfe is confident of getting thirty or forty more revolutions at the least, as he only had 330 revolutions, and steam blowing off abundantly. When he decided to use a balance rudder, he had never heard of a similar vessel being fitted with one. With regard to the air pump, he could not understand how an ordinary air or feed pump could work noiselessly at from 300 to 400 revolutions; so he designed special pumps, the air pump with two buckets in one barrel moving in opposite directions, and dividing the stroke between them. It has turned out a great success, works noiselessly at any speed, and Mr. Selfe informs us that he gets 26½ inches to 27½ inches of vacuum; the feed pump also works well. In the present case the blower is driven direct by friction rollers made of disks of leather, brought into contact with a large wheel or pulley on the engine shaft, and a small pulley on the fan shaft, by a pair of levers worked by a screw in such a way as to nearly equalize the pressure on the fan bearings. The fan is of a silent type, with gun metal frame and steel blades of No. 30 gauge, and works well. A turn of a hand wheel throws the leather pulleys out of gear, and stops the fan at once. The boiler is of the Belpaire fire box type, with Cudworth's mid-feather. The engine is all steel and wrought iron, except the cylinders. The crossheads and guide blocks are all forged of steel in one piece to save height, and few engines of 14 inch stroke with such long connecting rods have ever been made so low before. The steel plates were telegraphed for from England, but the steel for the engine and screw, copper for fire box, and other materials, had to be rummaged out from all over the colony, and Mr. Selfe had often to adapt what he could get. The propeller blades are of hammered steel on a wrought iron boss.

Our engraving below is from a photograph. The engine has two cylinders, 11 inches and 10 inches diameter by 14 inches stroke; the boiler has 300 1½ inch tubes; the pressure is 140 lb.; the length of the boat is 80 feet; beam, 10 feet 3 inches.—*Engineer.* Sc. Am. aug 24 79

From July 18 1879

In an electrical apparatus for controlling unmanageable horses, shown by M. A. Engström, of Paris (Stand No. 664), a peroxide of iron battery, which lasts for a long time without attention, sends a current, through the reins, to the bit, and prevents the horse from keeping it between his teeth. A similar arrangement cures a horse of crib-biting. In a new jointed buckle for harness, the middle tongue or tang is withdrawn to facilitate unfastening. A first-class honourable mention was accorded to M. Engström, whose inventions are in use by the Compagnie Générale d'Omnibus, Paris.

Jul. 1879

Peppard's Electric Torpedo Balloon.

For the SCIENTIFIC NEWS.

The Electric Torpedo Balloon is the invention of F. Peppard, of Basking Ridge, N. J. A partial description of it was published in a scientific paper in the summer of 1877. In this balloon the means of dropping the torpedo at any instant desired is the electric current. A small balloon capable of carrying from 10 to 500 pounds of nitro-glycerine is all that is desired. A couple of light electric wires, insulated and encased as one, are attached to a small electro-magnet just under the balloon. This magnet operates a simple and ingenious device, tripping it the instant the electric current is on, and thus allowing the suspended torpedo to drop. The wire plays out on a reel, and at the retained ends a ten-inch Grenet battery is placed in the circuit to supply the current. The operators get on the windy side of the enemy, fort or camp that is to be attacked or blown up, and with a sufficient length of wire attached they allow the balloon to waft up and out of range of shot over the object attacked, and the instant the desired position is reached (this can be readily observed by the use of the sextant glass) the operator presses the finger key, and the current thus sent into the electro-magnet under the balloon operates the detent, and like a flash of lightning, the torpedo drops straight down, and does not explode until it strikes, when it will explode. The dropping of a 500-pound torpedo is said to be sufficient to blow up a whole fort at once; it would, doubtless, kill many from the concussion of the air also. Thus in a few minutes forts could be blown to atoms, when in the ordinary way it would take days and weeks, perhaps, of hard fighting. Such a small balloon could probably be drawn back again after dropping the torpedo, by having a strong rope attached to it so as to reel it in, and thus save the balloon, magnet, &c. The device works instantly and accurately, and costs but very little. No person need be in the balloon.

The portable balloon now used in the army is large enough to carry up torpedoes, and is readily converted into an Electric Torpedo Balloon at a very small expense. Several Governments have inquired into the working details of this balloon, with a view of adopting it into service.

[We give the latter statement simply as communicated to us, the names of the Governments who are said to have made inquiries not having been supplied. We must also say that we cannot share the views of the writer of the article as to the precision with which the apparatus can be operated. Winds are notably variable both in speed and direction, and the movements of a balloon, either free or captive, are often quite peculiar. However, the proof of the whole matter is a subject of easy and inexpensive experiment, which may show our opinion to be unfounded. Could torpedoes be thus dropped over vessels, forts or armies in the field, they would prove a terrible means of warfare.—ED.]

98

METEOROLOGICAL REGISTERS[1]

THERE is now scarcely a meteorological observatory which is not provided with registering instruments. The number of these is already considerable,

Nature July 31 1879

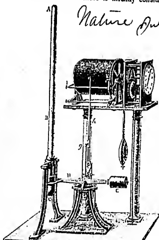


FIG. 1.—Registering Barometer.

and the methods of their construction are almost as numerous. At the observatory of Montsouris I have preferred continuous registration to registration by points, and the tracings effected by a fine metallic point on glazed paper blackened with smoke to the use of the pencil or to the *gaufrage* by pressure or by shock.

The barograph of Montsouris is a barometer-balance devised by P. Cecci, and latterly adopted by P. Secchi. The barometric tube A B (Fig. 1) is of iron, of 3 centimetres internal diameter, and of the same calibre throughout its length. It is fixed, and has, at its lower extremity, a cylindrical plunger, the full section of which is equal to the vacuum section of the barometric tube. The cistern, C, is of steel, and suspended to one end of the beam of a balance, D, the other end of which carries a counterpoise. The centre of gravity of the weighted beam coincides, as nearly as possible, with the central knife-edge, so as to render the equilibrium indifferent. Hence it results that when, in consequence of a rise of the barometer, a part of the mercury rises from the cistern into the tube, the former, thus rendered lighter, tends to rise, with the effect of introducing into the mercury of the cistern a greater length of the cylindrical plunger. Equilibrium is only re-established when (the volume of mercury displaced by the plunger being equal to that which corresponds in the tube to the increase in height of the barometric column) the level of mercury in the cistern returns to its constant point, and when, consequently, the apparent weight of that cistern has resumed its fixed value. The needle, *h*, of the beam of the balance marks its displacements on the surface of the blackened cylinder, K. It only remains to read the indications. To do this as accurately as possible, the support of the cylinder carries an electro-magnet, the armature of which is provided with an arm bearing a metallic point.[1] In ordinary weather this point is fixed, and traces on the cylinder a datum-line from which the ordinates of the barometric curve are measured; but every hour the electro-magnet is acted on by a clock, marking the time on all the registers; the point departs momentarily from the line, and makes a clear stroke, which is reproduced at the same instant on the other cylinders. At the end of each week the cylinder is taken away, to be replaced by another kept ready, and is placed on the reading apparatus.

This apparatus (Fig. 2) consists of a horizontal steel bench, *fg*, provided on its upper surface with two columns, *h h'*, intended to support the axis of the cylinder, and on a vertical stand with two microscopes, which may be moved either separately or together in a horizontal direction. By means of an endless screw a movement of rotation on its axis may be communicated to the cylinder for the purpose of presenting successively to the microscopes the various faces of the cylinder. The microscope *b* is always pointed on the datum-line, and it is to follow this line in its accidental displacements, that the two microscopes may be moved together by the action of an adjusting screw. The microscope which points to the traced line carries at its focus two crossed threads, one horizontal and the other vertical. At each hourly reading one of the horizontal tracings on the datum-line is brought under the horizontal thread of the microscope. But, as the barometric curve often presents inflexions of which it is useful to note the exact time, the critical point of this curve being brought under the movable microscope *a*, a second horizontal thread, movable by a micrometric screw, serves to measure the distance of this point from the hourly mark immediately preceding.

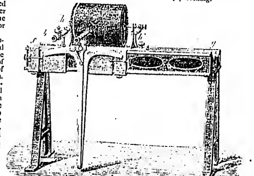

FIG. 2.—Micrometer for reading curves traced by the register.

The microscope *a* is supported at the extremity of an arm of a lever the length of which is equal to that of the barometric needle; it describes, consequently, an arc of a circle of the same radius as the point of the register. This second microscope has a cross of threads like the first, but without a movable thread. The first microscope being pointed to an hourly sign, the axis of the second is directed to the corresponding point of the curve. The sine of the angle of position of its lever, multiplied by a constant factor and increased by a number equally constant, gives the height of the barometer at the moment selected. When the reading of the curve is made and verified, the sheet of blackened paper is taken off the cylinder and soaked in a weak solution of gum-lac or of copal in alcohol. By this means the smoked sheet is "fixed," and thereafter put in a portfolio.

The feeblest barometric variations are thus shown with great fidelity, and by examination of the curves we readily recognise the influence which the dynamical state of the atmosphere exercises in increasing or diminishing the weight of its pressure on the ground. It should be added that the uniformity of the calibre of the barometric tube annuls almost completely the action of temperature on the indications of the instrument.

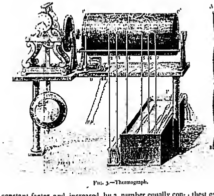

FIG. 3.—Thermograph.

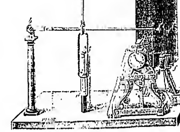

FIG. 4.—Register of the Atmograph.

two curves shows what becomes of

The thermographs act in an analogous way, except that the motor is here formed by a Bourdon tube of hammer-hardened copper, with a very elongated elliptical section, and twisted into a sort of spiral, the thread of the spire varying from 2 to 3 centimetres, according to the purpose for which it is intended. A B (Fig. 3) represents one of these tubes, forming a little more than one spiral. This tube is exactly filled with alcohol, and closed at its two ends. The expansion of the alcohol compels it to untwist; but in order that its elasticity may be preserved, the internal pressure, corresponding to the highest temperatures to be reached, should not exceed 8 or 9 atmospheres. This pressure is all the greater in proportion as the thread of the spire is short. The twisted tube is fixed by one of its ends, the other free extremity bears the needle which gives the indications. At Montsouris this needle is 5 centimetres long, as is also that of the barometer. The process of reading the curves is thus exactly the same for all the needle registers. The new thermograph of Montsouris Observatory contains seven needles acting on the same cylinder. The first needle (No. 1, Fig. 3) belongs to the electro-magnet which traces the datum-line, and the hourly signs; needles 2 and 3 belong to the psychrometer; needles 4 and 5 record the temperature of the surface of ground exposed to the air without shelter; needles 6 and 7 correspond to the actinometer.

The psychrometer is formed of two twisted tubes placed outside on the north face of the wooden kiosk, which shelters the cylinder, and perpendicular to that face. Their furthest extremity is fixed, the other is prolonged through the wall of the kiosk by a stem of copper carrying the indicating needle. One of the twisted tubes is uncovered, and forms the dry thermometer; the other is covered with cambric, and kept moist by means of cotton-wicks dipped in small glass cups, connected with a Mariotte flask placed in the kiosk by means of a long and fine tube of caoutchouc. An instrument of this kind has been in use for fifteen months at Montsouris; its action is regular, and its sensibility very great.

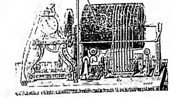

FIG. 5.—Anemograph.

The earth-thermometer is composed of two parts:—A thermometric reservoir of black copper is placed on the surface of a mass of vegetable mould, the top of which is flush with the platform of the roof of the kiosk; this reservoir communicates by a capillary tube of copper with a twisted tube placed in the kiosk under the cylinder of the register. When the temperature of the ground rises, a portion of the alcohol passes from the upper reservoir into the twisted tube, the pressure increases and the tube untwists; but the twisted tube itself and its capillary tube of

QUICK-ACTING ELECTRIC LENS-SHUTTER. Aug 8 18

[16026.]—As some of your correspondents have asked for an account of an instantaneous lens-shutter, I will endeavour to describe one, invented and used by my father. The construction will be best understood by reference to the following diagrams:—

FIG. 1

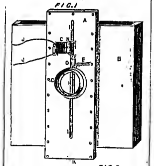

FIG. 3

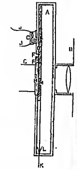
FIG. 2



The shutter apparatus is inclosed in a box made of fine cedar wood, which has an arrangement to enable it to be screwed on to the lens of the camera with which an instantaneous picture is to be made. Inside this box are two shutters or screens, which slide up and down inside the box, and run in grooves well black-leaded, to diminish friction. A groove is cut through on the outside of the box, and to one side of it an electro-magnet is screwed, connected to a battery, the wires from which are furnished with a touch-button, in order to make and break the current. Working on a pivot opposite to the electro-magnets, is a piece of iron (D) with two notches (F and F') cut in the lower part of it, and in these notches fit two small pins, which keep the shutters from falling; and a spring (E) is connected with the lower part of D, the piece of iron, and keeps it away from the electro-magnets, when the current is not passing. When the touch-button is pushed the current passes, and lets fall the lower shutter by drawing away the prop (F'); and while the current passes another prop (F) is put under the upper shutter (L). But as soon as the current does not circulate in the magnets, the spring (E) asserts its power by pulling away the other prop, and letting the top shutters fall and cover the mouth of the lens.

A is the shutter-box which screws on to the lens.
B is the camera.
C the electro-magnets.
D the iron with the two notches in it, in which rest the pins which support the shutters.
E the spiral spring.
F the upper notch, which when the current is not passing does not support the shutter, which is supported by the lower one; but when the current passes, the notch supports the top shutter; the lower notch (F') which when the current is passing releases the lower pin in the lower shutter and lets the shutter fall, but when no current passes the upper shutter is supported.
G is a lens screen made of brass.
H is the part of the shutter which runs in the guide.
I is a groove in the box.
J J are the wires to battery.
K is a piece of wire to push the shutters up with.
L is the uppermost shutter.
M is the lower shutter, made of thick cardboard, covered with a solution of lampblack and varnish.

Gateshead. Cameron Swan.

A New Electric Current Breaker.—A simple form of contact breaker is described by [illegible]. To the middle of a wire stretched horizontally is attached a platinum point which touches the surface of mercury held by a small vessel. The current passes through the wire, and over that part of the wire through which the current passes when all the apparatus in its normal state is a small magnet. This magnet, acting on the current, causes vibrations in the wire, and so breaks and makes contact. The number of vibrations can be readily modified by changing the length of the wire, and as high a number as 1000 breaks per second can be obtained. By passing an intermittent current over the wire, it can be set in vibration without the intervention of mechanical means. This happens when the fundamental note of the string is in unison with the pitch of the breaker.

Electrical Letter Boxes.—Among the recent applications of electricity is an attachment to street letter boxes, so arranged that if an attempt is made to rob the box an alarm will be instantly sounded at the nearest police station.

Sc Am Aug 23 1879

Journ of Sc Aug 1 1879

Electric Blowpipe.

At a recent meeting of the Academy of Sciences, M. Jamin submitted a new electric burner, which he also recommended to chemists and physicians as a blowpipe. Two carbons are supported vertically abreast, hinged below, and drawn together at the top by a spring. A current is sent up one, down the other, then round a rectangular circuit inclosing the two, and passing first round the first one by current attraction, the carbons are drawn apart, and the arc appears at the top and descends gradually, consuming one or both carbons. When the action of the rectangle is sufficient, the arc driven beyond the points is like a gas flame, and M. Jamin receives it on a piece of lime, magnesium, or zirconium, getting intense light. It is also so hot as to fuse the lime. For the electric light this burner has considerable advantages, since it has no mechanism and requires no preliminary preparation beyond a support and the carbon points. The size of the flame is almost doubled and the light is augmented. The new foci are very powerful, and the quality of the light is far better, and the arrangement of the foci is more advantageous, the greatest quantity of light being directed downward, where it is wanted, instead of up into the air, where it is useless.

It is now proposed that the officers undergoing a course of torpedo instruction on board the Vernon, at Portsmouth, shall also be required to familiarise themselves with the practical application of electricity to the art of war. The teaching element has not as yet been perfected, but proper instructors will, no doubt, be provided in course of time. Steam was got up in the Dread-nought on two occasions, and the first lessons in the production and management of the electric light were imparted. The turret ship is provided with a couple of lamps placed at each end of the flying deck, the current being generated by one of Wilde's electro-magnetic machines, the motive power for which is supplied by a strap from the forward ventilating engine. The illumination is produced by a couple of vertical carbon points, which are worked by hand. There is no subdivision of the current, so that only one light can be used at a time. Until lately, however, the after light could only be obtained by disconnecting the forward one and forming a new and separate connection with the commutator between decks. This method not only entailed great loss of time, but was attended with great difficulty. Now, however, an important improvement has been introduced, by means of which it is only necessary to shut off the forward connection, and the after light may be used at once. Some experiments have also been made with the Gramme machine on board the Bloodhound and a torpedo boat.

Nature Aug 7 1879

ELECTRICAL CLOCKS AND CLOCKWORK

In the year 1843 an electrical pendulum which forms the basis of nearly all succeeding systems of electrical clockwork, was patented by the late Alexander Bain. (See Fig. 1.)

The bob of the pendulum, C, consists of a coil of insulated wire. One end of the wire passes to the axis of the tumbler A T, the other, through the suspension spring S, to the plate P_1. P_1 P_2 are plates, say of zinc and carbon, and are sunk in the earth to form the battery. From P_2 a wire W_2 proceeds to N. M M is a horse-shoe magnet. Whilst A T leans against N, a current is passing, and C is

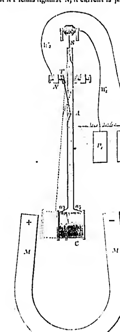

Fig. 1.

magnetic. C has its – and + poles facing the + and – poles of the horse-shoe magnet. Consequently the pendulum is driven to the left, but when it reaches a certain point, A T topples over, the current ceases, and the pendulum returns. The pendulum now proceeds on its swing to the right, but on approaching the limit of its oscillation, overturns A T again, the current is renewed, and the pendulum again propelled to the left. This action automatically repeats itself. Mr. Bain placed within the circuit of his pendulum any number of electrical dials. Fig. 2 shows the mechanism of these. C is a coil either in the line of W_1 or W_2. When a current passes C becomes magnetic, and oscillates between the magnets M M. At every swing of C a tooth, T_{11} of the wheel is gathered up by the detent D D. The click, K K, by holding a tooth, T_2, prevents the wheel returning whilst D is passing to the right.

The impulse on Mr. Bain's pendulum varied with the power of his battery, a condition fatal to good time-keeping. In 1849 Mr. Shepherd patented a system in which the current was employed to lift a slight weight or

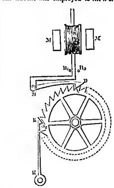

Fig. 2.

spring. The fall of this propelled his pendulum, and gave an impulse quite independent of any variation in the power of his battery. Fig. 3 shows one of his plans.

P P is the pendulum, W a weight, mounted on a lever W C A. W C A can move about a centre C, and is at present prevented from turning by the catch S S. When P P swings to the right, the lower screw in P P passes under E (see side view Z) and frees W C A. W C A, under the weight of W, propels the pendulum to the left till stopped by a

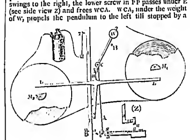

Fig. 3.

banking U. P P moves on and makes contact with T, whereupon a current passes, M_1 M_2 become magnetised, and attract L L, the vertical arm of which lifts W C A over the catch S S again. When P P leaves T the current ceases, and L L is carried back to its old position by the action of the spring R.

Mr. Bain's and Mr. Shepherd's are the leading types of electrical clocks properly so called, that is to say, of clocks which keep themselves going by electricity. But it

THE GLASGOW ELECTRIC FIRE ALARM SYSTEM.

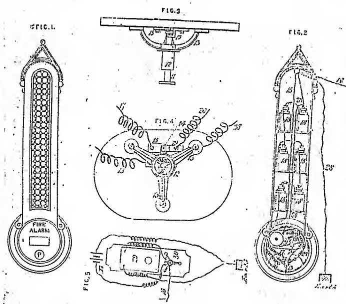
Telegraphic Journal Dec 15 1879

A SYSTEM of electric fire alarms has now been in use at Glasgow for some years, and has been very successful. The apparatus is very simple in construction, and little liable to get out of order. As the question of fire alarms is likely to receive more attention in this country than has hitherto been the case, a description of the Glasgow apparatus may prove interesting.

Fig. 1 shows the outward form of the signalling apparatus, which is placed at the corners of a number of the streets in the town. The arrangement

Fig. 2 shows an inside view of the wall-box. The upper part is occupied by batteries 18, placed on shelves as shown. In the lower part is fixed the push key 13 (which is shown on an enlarged scale by figs. 3 and 4) and the acknowledgment bell 21.

The push key 11 (fig. 4) is a tube having an annular head on its outer end, on which the word "push" is marked, and it is carried in a tubular bearing 12, fixed on a three-armed bracket 13. A helical spring is arranged inside the tubular bearing 12, to press the push key 11 outwards, and when the key is pushed inwards its inner end acts on a metal spring 14, and causes it to make a contact with a piece of metal 15, thereby closing the circuit



consists of a cast iron box, about 4 feet high, placed sufficiently high up on the wall of the building to which it is fixed to be out of easy reach of loiterers, but yet sufficiently low to be got at with a little exertion. To sound an alarm it is only necessary to depress the push key P, when a bell is rung at the fire station with which the apparatus is in communication, and on the receipt of the signal at that place an acknowledgment signal is returned, which sounds a bell placed in the lower part of the case.

of the wire to the district station, and sounding the bell at that station. The spring 14 is connected to the line wire 16 (figs. 2 and 4), and the metallic piece 15, into contact with which the spring 14 is pushed by the key 11, is connected by a wire 17 to the battery 18, shown in fig. 2 as occupying the upper part of the fire-alarm box. When the spring arm or switch 14 is not pressed in, it forms a contact with a metallic piece 19, which is connected by a wire 20 with the electro-magnetic bell 21 in the

ounted on the top of it. When

... method of correcting clocks was invented ... p. 35. M. Collin, Chevalier of the Legion of Honour, and has been largely made use of by him. Fig. 10 shows his standard clock, and Fig. 11 the clock to be corrected; the latter is regulated to gain a second or two per hour. A few minutes before each hour the lower of the two detents in Fig. 10 is lifted against the upper, and a current

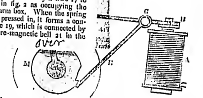

Fig. 12.

the clock, Fig. 11, reaches the hour, it allows the long

detent shown in the drawing to fall; this closes the circuit, and a hook attracted by the coil, catches a tooth cut in the escape-wheel, and holds it till the standard clock reaches the hour. At the hour the standard clock, Fig. 10, allows the lower detent to fall, and so breaks the circuit. Consequently the clock, Fig. 11, starts off side by side with the standard.

Mr. Ritchie, to whom we have referred before, has also devised a plan for correcting clocks by hourly currents. His clock, to be corrected in like manner, gains some second or two per hour. Fifteen seconds before each hour the lever D E (see Fig. 12) is attracted by the electro-magnet A, and a pin in the arm D would thereupon enter and catch a tooth of the escape-wheel, did the disc M allow the other arm of the lever E to move. When the hand reaches the hour, E falls, then D catches S and holds it till the cessation of the current at the sixtieth second of the governing clock.

Generally the use of a long telegraphic wire can only be commanded for a few minutes daily. Fig. 13 shows a very suitable arrangement to be adopted when this is the case. By means of the 24-hour disc the line wire is held in communication with the telegraph office until a

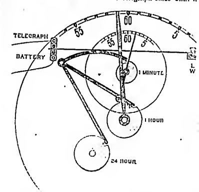

Fig. 13.

few minutes before the clock current is going to be despatched. The notch in the 24-hour disc will at last allow the system of levers to fall, but then the 1-hour disc supports them until about one minute before the clock current is coming; so that, till then, the line is being used for messages. The line wire has not been allowed to fall into circuit with the battery wire; this is still prevented by the 1-minute disc. At the sixtieth second precisely the 1-minute disc allows the line wire to join the battery wire, and out goes the clock current. Some seconds afterwards the 1-hour disc lifts the line wire back into communication with the telegraph office, where it stays for another twenty-four hours.

The Great Westminster Clock reports its own time to Greenwich by the following arrangement:—Some minutes before a signal is due, a lever is lifted by a slow wheel into such a position, that a pin in the next wheel at its coming rotation will catch it. The second wheel lifts it so much further that a pin in the escape wheel reaches it, presses two slight springs together, and sends off the signal.

A method of driving an electric dial was contrived by the late E. J. Dent. A powerful magnet was lifted through a coil of insulated wire by a strong tower clock movement. Every half minute the magnet was dropped a current was generated in the coil, which proceeded to the dial and moved the hands. A plan on the same principle has lately been used for driving a number of small dials. A pendulum having a hollow coil of insulated wire for a bob, is by a heavy weight kept oscillating over a system of magnets. Currents are generated in the coil which proceed to the dials and work them.

Only the principal inventions in electrical clocks and clock-work have been indicated in this article. Since the year 1843 upwards of thirty patents have been applied for for improvements in such clocks and clockwork. It will be seen from this the subject, though not a wide one, is extensive.

Mr. Ritchie kindly lent diagrams 5, 6, 9, 12, and 13 to illustrate his plans, and M. Collin 10 and 11. Figs. 1 and 3 have been arranged to exhibit their working with clearness.

LES POISSONS MAGIQUES

Un ingénieux physicien, M. de Combettes, ingénieur civil à Paris, s'est attaché à construire un grand nombre de jouets et appareils scientifiques à l'usage de la jeunesse, parmi lesquels nous signalerons la curieuse expérience que nous représentons ci-dessous.

Un bocal cylindrique rempli d'eau tient en suspension des poissons de fer-blanc, analogues à ceux que les enfants promènent à la surface de l'eau à l'aide d'un aimant. Mais ici le mécanisme est caché; à la

Expérience des poissons magiques mis en mouvement par l'électricité.

volonté de l'opérateur, les poissons accomplissent un mouvement de rotation, tantôt dans un sens, tantôt dans un autre. Le secret de cette expérience s'explique facilement de lui-même par la figure ci-dessus.

Dans le socle de bois qui supporte le bocal est caché un petit moteur magnéto-électrique qui agit sur le fer doux dont les poissons-flotteurs sont munis. Quand on fait passer le courant, le petit moteur de M. de Combettes se met à tourner et entraîne avec lui les petits poissons, qui nagent dans le liquide. Le mouvement giratoire est changé à volonté, à l'aide d'un commutateur.

Le Propriétaire-Gérant : G. Tissandier.

Electric Blowpipe.—At a recent meeting of the Academy of Sciences, M. Jamin submitted a new electric burner, which he also recommended to chemists and physicists as a blow-pipe. Two carbons are supported vertically abreast, hinged below, and drawn together at the top by a spring. A current is sent up one, down the other, then round a rectangular circuit inclosing the two, and passing first round the first one by current attraction the carbons are drawn apart, and the arc appears at the top and descends gradually, consuming one or both carbons. When the action of the rectangle is sufficient, the arc driven beyond the points is like a gas flame, and M. Jamin receives it on a piece of lime, magnesium or zirconium, getting intense light. It is also so hot as to fuse the lime. For the electric light this burner has considerable advantages, since it has no mechanism and requires no preliminary preparation beyond a support and the carbon points. The size of the flame is almost doubled and the light is augmented. The new foci are very powerful, and the quality of the light is far better, and the arrangement of the foci is more advantageous, the greatest quantity of light being directed downward, where it is wanted, instead of up into the air, where it is useless.

Electric Inscription of Words.—The transmitting apparatus is a microphonic speaker, the carbons of which instead of being pressed by a spring, are simply maintained in contact by the pressure of a small piece of paper folded in the form of a V. The vibrations of the diaphragm of the receiving apparatus cannot be written, since the movements of the style, however delicate the apparatus, can scarcely be distinguished upon the lamp-black." To enlarge the magnetic vibrations of the receiver the cover and the diaphragm of a Bell's telephone are taken away, and on the wood of the instrument there is fixed the end of a small, stiff steel spring. The other end of the spring abuts on the surface of the magnetic nucleus surrounded by its coil; to this extremity is soldered a small mass of soft iron, weighing about 10 grms., and upon this mass and in the produced line of the axis of the spring is fixed a light style of bamboo, 10 centimeters in length and terminating in a slender whale-bone pen.—*M. Boudet* July 26 1879

Mining & Sc Press

We call special attention to the advertisement of "*Edson's Recording Pressure Gauge and Electrical Alarm*," as it is an indispensable attachment, in order to completeness, to every water-works system, the "charts" showing at all times past and present the height or pressure in every reservoir or pipe to which it is connected, and *every reduction* in such pressure, as well as to define the precise time of day or night, and responsibility may be placed on the proper persons, unless such variations may be traced to other causes. NOUVEAUX POLYSCOPES

DE M. TROUVÉ

La Lumière Electrique Aug 21 879

Toutes les personnes, en France, qui se sont occupées d'électricité connaissent l'ingénieux instrument que M. Trouvé,

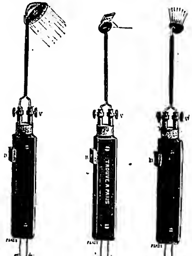

Fig. 1.

son inventeur, a nommé polyscope. Voici pourtant que des journaux étrangers attribuent au Dr Nitze, de Vienne, l'invention d'un appareil consistant en un tube de verre pouvant servir de sonde et portant dans les organes un fil de platine rendu lumineux par un courant électrique. M. Trouvé n'a pas de peine à établir que cette idée, qui est celle qu'il a réalisée, n'est pas nouvelle, et que d'ailleurs il l'a mise en œuvre beaucoup mieux. L'éclairage intérieur des cavités par l'électricité a été proposé à Paris, en 1867, par le docteur Brink, de Breslau; l'idée fut développée par le Dr Millot, et M. Trouvé exposait son appareil dès 1873. Son dispositif est beaucoup plus simple que celui du Dr Nitze. Le principal inconvénient étant la chaleur, ce dernier s'efforce de l'enlever à l'aide d'un courant d'eau; plus habile, M. Trouvé a réussi à ne pas la produire en excès. Dans ses petits appareils

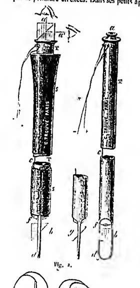

Fig. 2.

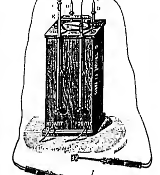

Fig. 3.

du genre de ceux qui figurent ci-dessus (fig. 1) l'électricité est envoyée par une batterie secondaire de Planté munie d'un rhéostat de nature spéciale, en sorte que le courant est réglé avec une précision absolue; le fil est très-fin et la chaleur produite est assez faible pour être très-bien supportée.

Au reste, une des preuves de l'invention est le perfectionnement; on en signale de très-importants apportés par M. Trouvé. D'abord, l'introduction des prismes à réflection totale et à grossissement, permettant de voir à côté de l'appareil les parties qu'il éclaire à angle droit, et d'explorer ainsi complétement une cavité telle que la vessie : la figure ci-dessus (fig. 2) donne l'idée de la disposition de l'appareil.

Ensuite, la disposition, sur une même source électrique, de deux circuits pouvant porter l'un l'appareil d'éclairage, l'autre un appareil cautérisant; l'opérateur peut, à l'aide de ce système figuré ci-dessus (fig. 3), n'avoir besoin d'aucun aide et n'éprouver aucun embarras d'instruments.

Au reste, ces appareils sont passés, assure-t-on, dans la pratique : les Drs Péan, Trélat, etc., en font usage et s'applaudissent de leurs résultats. L'appareil est important et il nous a paru utile de réclamer pour la France et pour un de nos plus habiles constructeurs l'honneur de son invention.

105

Rock Drilling by Electricity.—The application of electricity for the purpose of drilling or boring rocks has been suggested by M. Gaston Plante, the inventor of a process of engraving on glass by the same agency, which was made known in 1877. In the latter process, one of the electrodes conducting an electric current of high tension, being brought in contact with the glass, in presence of saline solution, acts like a graver or diamond, by tracing grooves in the surface of the glass, and even digs into it quite deeply. In spite of its great hardness, rock crystal can also be attacked by the same method; and, if not engraved regularly, it at least cracks into small fragments, and is finally disintegrated. Under conditions analogous to these, the electric current might be substituted for diamonds in the operation of drilling rocks. M. Plante states that electrodes of platinum would not be necessary, for here it is not the metal of the electrode that is affected, but the silicious matter, in contact with a saline solution. Metallic points or projections, suitably located at the extremity of the drill, isolated on a part of its length, and actuated by a rotary movement, would lead the electric current to the surface of the rock to be pulverized, and would thus replace those numerous and expensive diamonds which are set in the head of the drills employed in the present system of rock-boring. L'électricité appliquée à la surveillance des timoniers.

La Correspondance Scientifique aug. 1.2.1879

Suivant la *Nature* de Londres, on viendrait de faire une application très ingénieuse de l'électricité à la navigation. Un Anglais, M. Henry Severn, aurait réussi à établir, dans l'intérieur du navire, une sorte d'instrument à l'aide duquel le capitaine est averti au moyen d'une sonnette dès que le bâtiment cesse de suivre la route prescrite. Cette sonnette est mise en mouvement d'une manière automatique par toute la déviation de la route indiquée à l'avance. Le timonier ne pourrait changer de direction sans qu'un témoin vigilant avertisse à l'instant le capitaine de la faute commise.

En supposant qu'en quittant le pont, le capitaine ait donné l'ordre de suivre une direction, il place l'aiguille de l'instrument à un certain angle, et au lieu d'avoir comme aujourd'hui à veiller constamment sur la boussole pour savoir si ses ordres sont suivis, il s'en remettrait à l'appareil de M. Henry Severn qui l'en informe par son silence, et, en cas contraire, l'avertit par son tintement. L'instrument ne cesse de résonner que quand le bâtiment a repris la marche prescrite.

Deux index métalliques sont placés au-dessus de la rose des vents de la boussole : l'un à bâbord, l'autre à tribord de la direction choisie, c'est-à-dire l'angle de route étant la bissextrice de l'angle formé par les deux index et la projection du centre de suspension de l'aiguille. La grandeur de cet angle est déterminée par la latitude que le commandant laisse au timonier pour les embardées qu'il est obligé de faire soit à bâbord, soit à tribord. Si la rose des vents, qui, comme on le sait, est mobile avec l'aiguille, porte une pointe métallique, que le courant d'une faible pile soit introduit par l'axe, le contact avec les index ne peut se produire sans que le circuit soit fermé.

Il est clair que si le navire sort des limites angulaires prescrites, un courant peut s'établir et une sonnette d'alarme le mettre en action jusqu'à ce que le navire reprenne sa route.

La sonnerie peut être établie n'importe où, et, par conséquent, rien n'empêche de la placer dans la chambre du capitaine.

La question à résoudre est de savoir si ce dispositif nuit à la disposition de la boussole.

C'est une question à laquelle l'expérience seule permettra de donner une réponse.

Nous reviendrons sur cet appareil quand nous aurons entre les mains des procès verbaux d'expériences.

Mais il nous parait incontestable que cette nouvelle application de l'électricité appelle inévitablement l'attention sur la boussole circulaire de M. Duchemin, qui parait avoir une force directrice plus grande et se prêter à merveille à l'application du système de M. Henry Severn, quelle que puisse être sa valeur

V.-D. Costes.

An electric target—that is, a target which by means of electricity Sc. American Sept. 1879 ... another target set up at the firing station, the exact spot where a bullet strikes, and thus does away with the necessity of employing a marker to signal the result of each shot—has been lately perfected, after years of labor, by a Swiss locksmith.

La Lumière Électrique

DU ROLE DE L'ÉLECTRICITÉ

DANS LES DÉFENSES SOUS-MARINES

aug. 15/79

L'officier de mer, depuis quelques années à peine, est appelé à se servir couramment d'une nouvelle force, mise par la science entre ses mains. Les mines électriques sous-marines, ou torpilles, sont venues augmenter le cercle des études variées et nombreuses du marin. Tout en continuant à perfectionner les machines, tout en poussant encore plus loin la puissance formidable de leurs organes, le navigateur moderne a dû mener de front l'augmentation du calibre et de la portée du canon pour l'attaque, et trouver le moyen d'alourdir la cuirasse pour la défense, sans toutefois retarder la marche du bâtiment. Mais voici qu'aujourd'hui l'électricité vient prendre dans la marine une place des plus importantes, soit qu'il s'agisse de défendre la côte natale, soit qu'il importe de soutenir à l'étranger l'honneur du pavillon. Quelques appareils sûrs et peu compliqués ont suffi pour faire, d'un geste, voler en éclats ces canons, ces cuirasses, et ces admirables machines produites à grands frais par des armées de travailleurs. Est-ce là un progrès? Sans aucun doute, en ce qui concerne les peuples civilisés, si l'on convient que la guerre est plus funeste à l'humanité par les longueurs que par les plus meurtriers engagements du champ de bataille. Le progrès militaire est l'emploi des moyens les plus simples pour obtenir les plus puissants effets; mais cette simplicité même devient, si l'on pense aux peuples à demi sauvages, un obstacle dangereux à la civilisation. Les Chinois, les Japonais connaissent aujourd'hui l'usage de la torpille. Dans un avenir prochain, les plus justes réclamations du monde civilisé ne seront-elles pas tenues en échec devant une rade par quelque gueneur à demi nu chargé de presser un bouton de cuivre au moment où le port va être forcé? Si, de plus, les côtes attaquées sont défendues par des obstacles naturels s'opposant au débarquement, la marine se trouve dès lors réduite à l'impuissance, et ne peut reprendre son influence à moins qu'elle ne trouve dans l'électricité elle-même, probablement, un moyen nouveau pour se protéger de la torpille, si difficile à paralyser dans l'état actuel de nos connaissances.

Nous aurions donc beaucoup à dire sur la torpille et sur les différentes manières de l'employer. Quelques lignes au contraire suffiraient pour résumer les obstacles très-imparfaits que l'on tâche de lui opposer.

Nous offrons aux abonnés de la « *Lumière électrique* » un résumé succinct des divers systèmes employés par les grandes puissances européennes. Nous n'entrons pas dans des détails spéciaux en dehors de l'électricité; détails importants, croit-on, mais bien plus probablement tout à fait insignifiants, sur lesquels, en tout cas, chaque puissance s'efforce de garder le secret, tout en cherchant à connaître à fond les fonctionnements étrangers. Ceux de nos lecteurs qui n'ont pas eu l'occasion de se rendre compte de cet intéressant emploi de l'électricité verront peut-être entre ces lignes surgir tout à coup à leur pensée quelque application utile à notre flotte, quelque moyen tout nouveau à proposer pour la défense de nos côtes. C'est surtout, nous le répétons, dans la neutralisation de la torpille que l'on cherche à progresser.

Trouver un moyen secret, permettant, sans quitter le navire, de paralyser la torpille ennemie à dix mètres ou plus de sa verticale, serait l'écroulement de tout le système de protection électrique d'une côte.

Un autre progrès plus important encore et réalisable à bref délai, croyons-nous, serait l'invention d'un projectile électrique amortissable, c'est-à-dire tombant à pic sans rebondir à plus d'un mètre, dès qu'il a touché l'ennemi, puis éclatant sous l'eau à 3 mètres de profondeur par les moyens aujourd'hui connus dans toutes les marines, c'est-à-dire es pistons hydrostatiques. Ce boulet n'aurait pas besoin d'une grande force de projection, porterait à 200 ou 300 mètres seulement, et ne remorquerait aucun fil; il contiendrait sa source d'électricité.

107

Ce boulet électrique amènerait la suppression de l'artillerie perfectionnée et de la cuirasse, le jour où il pourrait être lui-même lancé par un petit bâtiment très-rapide s'avançant à toute vitesse à petite distance de l'ennemi. Or ces bâtiments existent déjà en dimensions réduites; nous en parlerons à propos des torpilles portées à toucher les flancs des attaquants de haut bord.

Les torpilles électriques employées de nos jours peuvent se diviser en deux catégories : celles de la *défense fixe* destinées à barrer un passage et établies dans une position déterminée sur le fond, et celles de la *défense mobile* légères, maniables, portées par les grands bâtiments dans leurs combats au large, ou par des embarcations rapides destinées à courir sur l'ennemi en vue.

DÉFENSES FIXES. — DÉFENSE D'UNE PASSE.

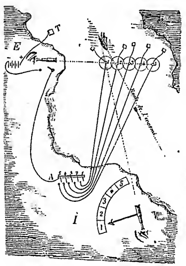
La défense fixe prend ses positions d'après la configuration des côtes et des vallées sous-marines. Tout ce qui a trait à cette branche spéciale pourra donc être pesant, laborieux à établir, mais devra être de longue durée sous l'eau, et d'un effet d'autant plus puissant que la ligne de torpilles est la dernière défense des assiégés.

La torpille étant une masse de matières explosibles enfermées dans une carcasse en fonte ou en tôle et dont l'effet est rendu plus violent par la charge d'eau qu'elle supporte, elle devra se trouver toujours au moins à 3 mètres de profondeur. Le cercle d'action dangereuse produit à la surface par l'explosion, varie avec la profondeur, la charge, la résistance de la carcasse. — On l'estime suffisant en pratique quand il a 12 à 15 mètres de diamètre; les torpilles seront donc mouillées à 30 mètres les unes des autres en travers de la passe, mais une rangée unique a un inconvénient : la commotion produite par une torpille brise souvent par contre-coup celles qui en sont voisines. — Il vaut donc mieux mouiller les torpilles en quinconce. On les dispose ainsi en groupes qui explosent en bouleversant une grande surface.

La gerbe soulevée par une torpille se compose dans son ensemble d'un volume conique sous l'eau, dont l'axe est toujours vertical, et l'angle au sommet, partant de la torpille est plus ou moins aigu suivant la profondeur; au-dessus de l'eau la gerbe proprement dite est cylindrique à la base, conique au sommet; son diamètre, nous l'avons dit, doit être de 15 mètres environ. — Sa hauteur atteint de 25 à 50 mètres, suivant la quantité de poudre et l'immersion. Tout autour de la base, l'eau est gonflée et houleuse, mais sans danger même pour une embarcation qui n'aura, à cette distance de 8 mètres du centre, rien à redouter qu'une forte pluie retombant sur son avant, tandis qu'à 2 mètres devant elle le plus fort bâtiment serait complétement désuni par l'effet du marteau d'eau ascendant. — Il faut donc, dans l'usage des torpilles dormantes, arriver à produire l'explosion au moment précis du passage du navire sur la verticale de l'engin. — De même, pour les torpilles légères portées au bout d'une perche inclinée dont le bout est immergé à 3 mètres sous l'eau, il suffit que cette perche ait 8 à 10 mètres de long pour que l'embarcation n'ait aucun dommage sérieux.

La précision du tir nécessaire à la défense fixe a été l'ob-

jet de dispositions variables suivant les puissances et la configuration des passes. S'il est permis d'employer le mot dans la circonstance, la plus élégante de ces dispositions est celle qui place le guetteur de la passe sur un point élevé voisin de la mer, où il voit, enfermé dans une chambre obscure, se peindre sur un tableau blanc l'image de la passe. On a préalablement envoyé un canot à l'aplomb de chaque torpille; il a décrit autour de ce centre un cercle de 7 mètres de rayon, cercle dangereux, et on a tracé en même temps sur le mur de la chambre noire la trajectoire de ce canot, un numéro indique quelle pédale il faudra presser lorsque l'ennemi viendra se peindre au même endroit. — Ce système employé d'abord en Amérique a été vite abandonné, les



ellipses correspondant aux torpilles éloignées étaient trop aplaties pour bien juger la situation de l'ennemi surtout avec de la houle. De plus, le point élevé était en vue et servait de but au tir de l'assaillant.

On emploie généralement aujourd'hui le système de visée simultanée par deux postes assez éloignés l'un de l'autre et aussi ras de terre que l'on veut; l'un de ces postes dit *extérieur* est sur la ligne même des torpilles; l'autre, le poste *intérieur*, est autant que possible sur la perpendiculaire à cette ligne. Au poste extérieur, une lunette fixe est braquée dans la direction des torpilles, un commutateur à pédale est à portée de la main du guetteur. — Dans un coin, une forte pile d'inflammation de 30 éléments Bunsen modifiés (bichromate de potasse autour du charbon, et eau saturée de sel marin autour du zinc.) — Enfin un appareil télégraphique pour parler au poste intérieur. — Celui-ci contient une lunette qui se meut horizontalement, entraînant une queue qui se déplace sur un arc de cercle dont chaque secteur porte un numéro correspondant à une torpille connue. — On suit donc l'ennemi avec cette lunette, et un autre opérateur presse sur un clavier A la touche portant le numéro indiqué par la queue de la lunette sur le secteur.

Le diagramme ci-contre donne la marche du courant : pôle de la pile, plaque de terre T, plaque de terre de la torpille 1, 2, 3, etc., amorce de celle-ci, conducteur sous-marin, clavier des commutateurs, fil des postes, commutateur du port extérieur E, pôle négatif. On voit que l'œil du poste I suivant le navire pressera en ce moment-ci la pédale n° 1 en continuant à suivre l'ennemi, il pressera bientôt la pédale 2 en abandonnant la pédale 1. Mais à ce moment l'œil du poste I voit le bâtiment sur la ligne, presse son commutateur et le circuit fermé fait sauter 2 seulement.

Le télégraphe qui relie les deux postes servira à bien désigner le navire à suivre pour que les deux guetteurs n'aient qu'un même objectif convenu d'avance.

Cette entente préalable est l'inconvénient du système à deux postes, mais leur position dissimulée, et toujours protégée par un fort, les met à l'abri des projectiles ou d'un coup de main, seul moyen encore connu de paralyser réellement une ligne de torpilles.

L'installation d'un pareil système est une affaire de mouillage et de manœuvres maritimes sans rapport avec le jeu de l'électricité. Il suffit donc de dire que les conducteurs affectés à chaque torpille ont été éprouvés d'abord à terre par les méthodes connues de conductibilité et d'isolement à épreuve forcée (6 couples Leclanché). Un conducteur partant du clavier est soudé dans la torpille de poudre à une plaquette de zinc reliée elle-même à une des branches de l'amorce, l'autre branche de celle-ci est soudée au fil de la plaque de terre au moyen d'un bout de conducteur assez long pour qu'on puisse au besoin élever au-dessus de l'eau la plaque de terre. En traversant la torpille, le conducteur est, bien entendu, luté avec soin dans l'orifice unique servant à son entrée et à sa sortie. Dès lors on peut, une fois les torpilles en place et tout le réseau établi, procéder aux épreuves qui ne seront faites qu'une fois avant d'abandonner tout ce système au fond de l'eau. — Puis, journellement enfin, une partie de ces épreuves pourra se faire sans sortir des postes.

Les Anglais ont adopté la concentration, dans un poste indépendant, des divers appareils que nous venons de mentionner. — Aux postes E et I, ils ne laissent que des lunettes pour suivre le but; mais ces lunettes, par le moyen d'un fil télégraphique, indiquent au poste central tous leurs mouvements sur une planchette où deux aiguilles se meuvent parallèlement aux lunettes qui les actionnent. Quand ces aiguilles récepteurs viennent se croiser sur la carte à l'endroit où gît une torpille, le poste central fait feu en conséquence.

BROSSARD DE CORBIGNY,
Lieutenant de vaisseau.

(*A suivre.*)

Adaptation of Electricity to Useful Purposes.

Until the invention of the electric telegraph it had not been found practicable to apply the power stored up in electricity to useful purposes. Its nature and characteristics had indeed engaged the attention of scientific investigators for many years, and nebulous ideas of the possibility of utilizing it for the service of mankind had occurred to those who were engaged in its study, but without practical result. Finally Cooke in England and Morse in America, neither of whom belonged to the scientific fraternity, succeeded in solving the problem which had so long baffled the most able scientists of the world, and invented systems of electric-telegraphic communication which proved to be practical and successful. It is but justice, however, to concede that their inventions were only possible through the investigations and discoveries of the philosophers who for so many decades previously had made electricity a study.

These inventions have had an importance and a far-reaching effect, which probably was but dimly foreseen, even by the inventors or the enthusiasts whom they succeeded in interesting in their inventions. Within little more than the life-time of a generation they have revolutionized the social and business systems of the world. Year by year the telegraph is more and more indispensable, and has already become so essential that a total suspension of telegraphic communication, even for a day, would be regarded as a public calamity. The crude but effective apparatus at first used has been simplified and improved upon, and the capacity of conductors for electrical transmission has been developed and practically utilized, and these have become so familiar to the public that results which but a short time since would have been regarded as marvelous and scarcely credible, are now looked upon as of no very special note. Inventions which double and quadruple the available capacity of conductors are not regarded as worthy of special notice, and we are looking expectantly for the time when these results shall be notably exceeded, and six, eight, and even a larger number of circuits shall be regularly operated over a single conductor, as six and eight have already been worked in experimental trials.

The speaking telephone opened up a new field of telegraphic experience and research, and although but recently invented, has already been generally adopted for special and private lines. By means of telephone exchanges, which are being established in all parts of the country, a person is placed in direct oral communication with the persons and places of business of those with whom it is desired to confer, and thus business and social intercourse is facilitated and promoted. The number of telephones already manufactured and in use in this country is probably not less than 50,000, and is being increased as rapidly as they can be manufactured. It naturally makes its way more slowly in Europe, but is being extensively introduced there, and the American system of telephone exchanges is beginning to be looked upon with favor.

By the invention of the telephone we are enabled not only to communicate orally over considerable distances, but also to study the utterances of nature. The voices of the volcano and the earthquake, telephonically reported, reveal to us the titanic workings in the great laboratory of the earth. The lightning announces its coming before even the flash is visible. The pulsations of the vital fluid within our veins and arteries convey to the ear of the physician and surgeon valuable information of our physical condition. Daily new uses are found for the telephone and microphone, and it is not likely that these will be soon exhausted.

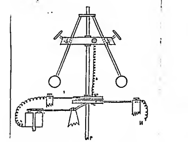
Electricity guards our buildings and property against the spread of conflagrations and the attacks of burglars and thieves; it gives us light rivaling almost the brilliancy of the sun itself; it pierces the hardest rocks and metals, and furnishes the motive power required to run our sewing machines. It traces our pictures, and prepares the plates for the printer; it regulates the movements of our clocks and plows our fields (though not the latter as yet to any considerable extent). It is, in fact, becoming the universal servant and agent of mankind, and it is impossible for us to conceive to what uses it may not yet be put for our convenience and benefit. So much has already been accomplished through electrical agency that the public mind is prepared to credit even the most marvelous achievements which may be claimed for it. It is indeed a wonderful manifestation of a force without doubt co-extensive with the universe itself, and one of the most useful and terrible agencies.—*Journal of the Telegraph.*

A NEW METHOD OF CONTROLLING THE DRIVING-CLOCK OF AN EQUATOREAL.* Eng Mechanic

THIS is a description of an automatic brake to be applied to a rapidly moving part of the mechanism of an ordinary equatoreal driving-clock whenever the normal velocity is exceeded.

As applied to my driving-clock belonging to a 9½inch reflector, it consists of the following parts:—A frame of brass, slotted so as to inclose, without touching, the centrifugal arms of the governor, is fixed to the upright axis to which these arms are attached, but is insulated from it: in the frame are two brass screws (only one of these need be in use) which can be regulated so as just to be in contact with the arms when the proper speed has been obtained. Two metallic wheels are fixed to the lower part of the axis, the upper of which is insulated from it, but connected by a wire with the frame in the upper part, and the lower one is in metallic contact with the axis. Two light springs are in contact with these wheels, and an electro-magnetic brake (as shown by the figure) is balanced so as to press lightly on the base of the lower wheel when no current is passing.

Four to eight small-sized Leclanché cells suffice to actuate this brake.



No current can pass until the weighted arms fly out so as to touch one of the screws in the upper frame; electrical contact is then made, the brake acts instantly, and immediately the arms drop an infinitesimal distance and contact is broken: this intermittent action goes on rapidly, and results in an extremely steady speed, the oscillations being so minute that they are barely perceptible, even with a magnifying power of 500 diameters.

I use a driving-weight of 40lb., and find that when this brake is in action 24lb. can be added without affecting the rate; and I feel sure that by varying the leverage of the brake, or the battery-power, or the size of the electro-magnet, that the weight *might* just as easily be doubled.

This control was devised in order to obviate the necessity of accurately balancing the telescope (when using a spectroscope, for instance), and to prevent the slackening of the clock's speed, which is frequently caused by a rapid fall in the temperature.

The idea was suggested by a description of a control for machinery invented by Mons. Marcel Deprez (see ENGLISH MECHANIC for March 14, 1879), which, however, is exactly the converse of the plan here described.

Of course I do not intend this simple method to compete with the more perfect, but also more expensive methods devised by Bond and Cooke and Lord Lindsay, but I can confidently recommend it as an excellent and cheap substitute for those who have not very perfect clocks.

* By R. C. JOHNSON, F.R.A.S., in the *Monthly Notices* of the R.A.S.

Electric Clocks

Nature Aug 21 1879

The various contrivances for electric clocks all depend on producing contacts with the pendulum, which is confessedly undesirable; and they nearly all produce these contacts when the pendulum is at rest at the highest point, which is the worst position.

There seems no reason why a pendulum with a coil-bob traversing over a short permanent magnet, as is usual, should not be independent of contacts. While descending the lower part of the stroke it reaches the magnet, and a current is thus excited in the coil, which is conveyed out at the knife-edges and works a switch; this sends a battery current through the coil for a short period while the pendulum is beginning its ascent, and so drives it forwards by repulsion from the magnet. The same process is repeated in the back stroke. The interval between the production of the excited current and the battery current, and also the duration of the battery current, may be regulated by a small pendulum whose single swing is equal to the interval, and which is liberated by the excited current. The details are so easily arranged that it is scarcely worth while to particularise them. Of course the battery current thus liberated by the excited current could be used for controlling other clocks.

The effect on the pendulum is thus restricted to the quicker parts of its swing; and consists of slightly retarding the descent, and accelerating the ascent, apart from all mechanical friction or contacts. Thus each action is produced at the most suitable time.

Possibly a pendulum cutting off heat rays from a thermopile might thus work a switch, and be even less affected than by producing an excited current in the coil-bob, as proposed above.

Bromley, Kent — W. M. Flinders Petrie

Debray uses wires of German silver in the manufacture of metallic laces. He colors metallic foils for the same purpose by depositing upon them iridescent films of oxide of lead. Litharge is dissolved in caustic alkali, and the resulting solution is decomposed by a current of constant intensity, the positive pole of the battery being in communication with the metallic surface to be coated. Engineering & Mining Sept 20 1879

ELECTRIC BRAKE FOR RAILWAY CARS.

In view of the tremendous speed attained by railway trains, it is a matter of the greatest importance to procure safe, reliable, and powerful brakes, which can be controlled from the engine or any other part of the train. Mr. Achard has invented a new and very ingenious electric brake, which is illustrated in the annexed cut taken from *La Nature*. Two Planté secondary batteries, each charged by three Daniell elements, are arranged on the first car, and two like batteries are provided in the last car. In the engraving the four secondary piles are united, but that does not affect the working of the device.

The current of the secondary batteries is conducted to the brakes of each wheel, the two wires running parallel with the train, with which wires the electro-magnets of the brakes are connected in such a manner that the brake operates when the circuit is closed. The electro-magnet, A, is rigidly mounted on a shaft suspended opposite the axle, B. If the current passes through the electro-magnet it is with great force drawn toward a sleeve, rigidly mounted on the axle, B, and is held against it with sufficient force to cause it to rotate with the axle, thereby winding the brake chains upon the shaft of the electro-magnet. The long arms of the articulated levers, C C, are raised by the winding up of the brake chains, and the brake shoes, D D, connected with the short arms of the levers, C C, are pressed against the tires of the wheels with great force. A brake shoe is provided on each side of the wheel so as not to break the journal box by undue pressure. To release the brakes it is sufficient to break the circuit, upon which the electro-magnet is released from the axle, B, and the chains are unwound. The commutator, H, is used to close or break the circuit, and may be located in the caboose of the engineer, in the last car or at any other convenient part of the train. The brake operates instantaneously, and sometimes produces such shocks that Mr. Achard has found it necessary to interpose resistances in the circuit to weaken the current proportionately. During the experiments made with this brake, on the Northern Railway of France, a train of thirteen cars, with a speed of forty-five and a half miles per hour, was stopped in twenty-one seconds and within a distance of seven hundred and five feet.

ELECTRIC BRAKE FOR RAILWAY CARS.

...ment upon it. These two papers were discussed together, and gave rise to a great deal of criticism. It was pointed out that the friction of the cup leathers attached to the pistons of the Foulis regulator was a variable quantity, and that the gun-metal linings of the cylinders were apt to become worn only in that part where the piston travelled most frequently, so that a ridge was formed at each end of its usual travel; hence, when the pistons are made to travel a greater distance than usual they are liable to stick. Both the Foulis and the Burton and West valves have, however, been in use for some time, and an elaborate series of experiments with the latter have been made at the South Essex Waterworks.

...ll pursuing their investigations in the hope of discovering improved means of carburetting gas, and as these are applicable to ordinary coal-gas, an account of their invention may be useful, though the inventors obtained provisional protection only. In the article above mentioned, we described a method of enriching gas for illuminating purposes by mixing with it the vapours of hydrocarbons generated by the heat of the flame in carburetting vessels in proximity thereto. The present invention relates to the construction and arrangement of the vessels for this purpose in such a manner that they can be readily charged with the hydrocarbon even while the gas is passing through them, while they remain always sealed against escape of gas. For this purpose the carburetting vessel is fitted with a feeding-tube which extends nearly down to the bottom of the vessel, or it may extend quite down to its bottom, and have small slits or holes through it close to the bottom. This tube is closed at the top by a cap, plug, or stopper, which may or may not be an air-tight fit. The hydrocarbon is fed into this tube at the top. When it is in liquid form it seals the bottom openings of the tube against passage of gas through them, or if it be in the solid form, such as the stick or rod of naphthaline described on p. 86, Vol. XXVIII., its lower part, in melting, forms the required seal while it is liquid, and remains a permanent seal when it becomes solid again by cooling. A portion of liquid hydrocarbon, such as paraffin, which does not volatilise at the temperature to which the vessel is subjected, may be in the first place poured into the feed tube in order to provide, before the naphthaline is melted, or when that or the other hydrocarbon used is exhausted, the liquid seal required. The feed tube may be external to the carburetting vessel communicating with it at the bottom, ... of ... size may be ... so that it may hold a store of hydrocarbon sufficient for supplying the carburetting vessel for a considerable period. Such feeding tube or vessel communicates with the carburetting vessel by a pipe connecting their bottoms, this pipe being kept sufficiently heated when solid hydrocarbon, such as naphthaline, is used, to enable it to flow to the carburetting vessel. In cases where it is required to charge the carburetting vessel of a high light, such as a sunlight, at or near the ceiling of an apartment, the inventors make the burners and carburetting vessel in one piece, separate from the gas supply pipe in the ceiling, balancing this piece by suitable weights with chains or cords passing over guide pulleys, and they provide at the mouth of the gas-pipe a trumpet-mouthed stuffing-box, so that when the carburetting vessel and its burners are raised to their normal ...ht joint connecting ...c. ...we illustrate the ... Bellet and Hallez ...ning by means of ...s of writings and ...produced by litho... ...acid-graving pro... ...coil, arranged in ...ployed. A metal plate is united ... poles by means of a wire, and the other pole is connected to the core of an ordinary blacklead pencil or suitable point by means of a very fine wire. On the metal plate is fastened by means of gum a thin sheet of paper previously dipped in water containing sea-salt. The induction coil is then set in action and the design it is required to reproduce is drawn on the paper attached to the metal plate with the pencil (or point) by which means the two poles are brought together, and the electric sparks dart continuously from the point of the pencil or point, and produce on the thin paper small holes corresponding with the lines of the design. The metal plate should be placed on some insulating substance. The design or writing thus finished, the metal plate is dipped in water and the paper carefully removed. The stencilling thus obtained, it is easy to transfer it to stone by inking a sheet of paper with transfer ink and then placing the stencil thereon and covering it with a sheet of white paper and pressing it sufficiently for the ink to pass through the holes in the stencil. A proof is thus obtained which can be transferred in the ordinary way. The transfer can also be made on zinc, by which a typographical stereotype may be obtained. In order to obtain an engraving or etching on metal it is necessary to proceed as follows:—A well-polished copperplate is covered with a thin layer of varnish. On this varnish a sheet of thin paper or suitable material is pressed, and upon executing the writing or design thereon with the electric pencil (or point) the electric spark will penetrate the paper and varnish at the same time and leave the metal bare at all parts touched by the pencil or point. The plate is then dipped in a nitric acid bath of 20deg.; the acid will attack the metal where not covered with varnish, and after two or three

SIR WILLIAM FOTHERGILL COOKE.

WILLIAM FOTHERGILL COOKE was born at Ealing, in the county of Middlesex, in the year 1806. His father, W. Cooke, was a doctor of medicine in Durham; and after a school education at that town he was sent to Edinburgh University to complete his studies. Like most of the famous electricians of that day, and even of our own day, he was not bred to the study of electrical science.

It was while engaged in a course of surgical training at Heidelberg that one day in March, 1836, he happened to witness an electrical experiment exhibited by Professor Moncke to his class, which greatly interested him, and planted the seed of inventive thought, which speedily grew into the first practical telegraph. The telegraph, like every other invention, including even the phonograph, was not entirely the work of any one man, but was led up to step by step by a number of different thinkers and experimenters. In 1820 Oersted discovered the fact that a current circulating in a wire has power to deflect a magnetic needle freely poised in its neighborhood; and Gauss and Weber subsequently applied this fact in devising and erecting a short private line of telegraph between the physical cabinet of the University and the Observatory of Göttingen. It was a similar contrivance to this which Professor Moncke showed to his students on that day when Mr. W. F. Cooke was present. It consisted of a battery, a conducting circuit of wire extending from one room to another, and a pair of rude galvanometers or coils of wire encircling suspended magnets. With this elementary apparatus Professor Moncke succeeded in exchanging visible signals between the two rooms by means of the electric current. Probably no other student in the room but the young Englishman saw the immense practical importance of such an arrangement. This side of the experiment struck Mr. Cooke so forcibly, that from that day he gave himself entirely up to scheming and pondering over the subject, and within three weeks after he had devised a practical working telegraph on the basis of the Moncke, or rather the Gauss and Weber apparatus. The plan involved the use of six wires, forming three separate circuits, for as yet Steinheil's great discovery that the earth itself would act as a return wire was not known; and each circuit operated a separate needle galvanometer. The alphabet or code comprised 26 signals, and he employed three keys to make and break the circuit, together with a rudimentary switch to alter the connections from "send" to "receive," or contrarily. In 1836 he also designed a mechanical telegraph on the musical box principle, in which the current passing through an electro-magnet attracted an armature which released a detent, and thereby permitted a barrel, studded with projecting pins, to revolve until one of the pins came into contact with a tangential lever, which broke the circuit, leaving an indicating dial, with the proper signal letter or figure exposed.

Cooke tried to get his new invention introduced on the Liverpool and Manchester Railway in the latter part of the same year, but the directors viewed the novelty with small favor, and condemned it as too complicated for their requirements, which was to transmit train signals along a tunnel. He therefore set himself to simplify his apparatus, and succeeded in doing so early in 1837, but by this time a pneumatic contrivance had been resorted to by the directors. Nothing daunted by this failure to get his schemes practically tested, Mr. Cooke continued to perfect his apparatus. He engaged in experiments to ascertain at what distance an electric current would excite temporary magnetism in the electro-magnet employed to move the detent of his mechanical telegraph; and consulted Faraday, Dr. Royet, and Professor Wheatstone on the point. It was on the 27th of February, 1837, that he first met Wheatstone, who had before that time been engaged in researches into the velocity of electric waves in solid conductors.

Cooke recognized that Wheatstone's knowledge and genius would be serviceable to him, and early in May, 1837, they entered into a partnership together with Mr. J. L. Ricardo, M.P., combining their ideas in a patent dated June 12 of that year. This patent described an improved form of Cooke's original invention, with five vertical galvanometer coils and astatic needles instead of horizontal ones, and having a diamond-shaped vertical face on which the five needles were pivoted, so that their relative positions could be seen at a glance. There were five separate circuits corresponding to the five needles, with one return wire common to them all. These five circuits were operated by five keys, and each signal was indicated by the relative motions of any two out of the five needles. This apparatus, since known as the "five-needle instrument," was first tried on the London and Birmingham and Great Western Railways, but was found expensive on account of the number of wires used, and subsequently abandoned. Nevertheless the "five-needle instrument," working in 1838-9, between the Paddington and West Drayton stations of the Great Western Railway, a distance of about 13 miles, was the first public telegraph in the United Kingdom, if not in the world. The original Paddington instrument now forms the chief relic of the Postal Telegraph Historical Department, and it is still to be seen on the occasion of every telegraphic fête of importance in London.

In the year 1840 Cooke established the Cooke & Wheatstone system on the Blackwall Railway, and in 1841 on a short line through the tunnel between the Queen Station at Glasgow and the engine house at Cowlairs Junction on the Edinburgh and Glasgow Railway. The following year the telegraph line from Paddington to West Drayton was continued to Slough near Windsor, and a great public interest in it was soon after excited by the clever capture of a Quaker named Tawell, who had committed a daring murder near Slough, and escaped by rail to Paddington, where, thanks to the original five-needle instrument, two detectives were waiting for him as the train drew up to the platform. In 1843 two more short lines were erected, one in Ireland and one in England, and worked by the Cooke and Wheatstone apparatus. In 1844 a line of considerable length, from London to Portsmouth, was also opened for traffic on this system.

Mr. Cooke was rewarded for his great public services in establishing the telegraph by receiving the fourth Albert gold medal in 1863, his name being preceded on the list of recipients by that of the immortal Faraday; and on November 11, 1869, Her Majesty conferred upon him the order of knighthood in recognition of his great and special services in connection with the practical introduction of the electric telegraph. In 1871 he was granted a civil list pension of £100 per annum.

The last two years of his long and prominent career were spent in great privacy until his death, on June 25, at Farnham, in the seventy-third year of his age, after he had lived to see the inventions which his sagacity forced upon civilization develop extraordinary powers and gradually spread itself over the whole world.—*Engineering.*

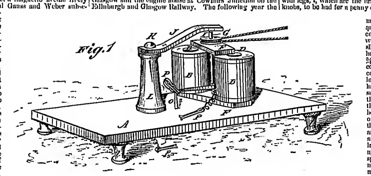
AN ELECTRICAL CABINET.

By GEO. M. HOPKINS.

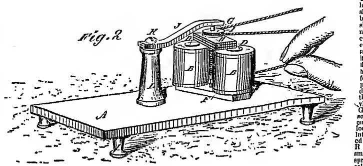
THE number of persons who are interested in electrical matters at the present time is enormous, owing to the impetus given to the electrical science by the invention of the telephone and the recent improvements in electric lighting. Many amateurs have taken up the subject as a pleasant field for experiment and study, with a prospect of a possible reward for the discovery of a really practical novelty.

To assist this class of experimenters, especially the younger ones, I have devised what I will call an electrical cabinet, containing a few parts which may be combined to form several different pieces of apparatus, and which, with slight additions, may be employed in performing a great variety of experiments.

The first engraving shows in detail, full size, the several pieces required. There should be two bed pieces, A, with holes exactly as they are shown in the drawing, and provided with legs, *l*, which are the ordinary black carriage curtain knobs, to be had for a penny or so at any hardware store.



ELECTRIC ENGINE.



MAGNETO MACHINE.

APPARATUS MADE FROM PARTS OF THE ELECTRICAL CABINET.

The following articles, which may be easily made, will be required: Two helixes, B, which consist of a thin wooden spool wound with 8 layers of No. 20 silk-covered copper wire. Two helixes, C, wound with about ¼ oz. of No. 34 silk-covered copper wire. Two soft iron cores, D, ⅜ in. diameter, a little longer than the helix, B, and having a threaded stem, *m*, of sufficient length to reach through the bed piece, A, and receive the nuts, E, two of the latter being required. The yoke, F, of soft iron, is drilled to receive the stems, *m*, of the cores, D, and having a small conical hole, *n*, in the center. F' is a soft iron armature, having a central aperture, *o*, for receiving the spindle, G. A compound bar magnet, H, is also fitted to the mandrel, G. The milled nut, I, which binds the armature, F', or the magnet, H, upon the spindle is grooved around its periphery for receiving a cord or belt. The mandrel, G, has a small hole bored through it near the shoulder, and is flattened at *p* by filing on diametrically opposite sides so as to remove a little more than a quarter of the circumference on each side. J is a curved piece of brass, having a small conical hole, *q*, drilled in it for receiving the upper end of the spindle, G. It has also a hole through the opposite end for receiving the bolt, K. The pillars, L, of brass or wood are drilled longitudinally to receive the bolt, K. The latter is provided with a nut, N. The spring, O, is bent into the form represented and flattened at both ends. Twelve or fourteen wire loops, P, and two wires, Q, bent into the form shown, and threaded at the lower end, are required. R is a vibrator consisting of a small armature, *r*, soldered to a spring, *s*, which is drilled to receive the bolt, K. A small hole is drilled in the end of the armature to receive the wire of the bell hammer, S. U is a strip of brass bent into the shape shown, and having near one end a small hole, *t*, for receiving a screw. For the sake of convenience I have placed above each cut a figure representing the number of pieces of each required.

With these simple parts, which may be made without further description, a great variety of experiments may be tried.

Simplest among the pieces of apparatus that may be made is the sounder, shown in Fig. 3. There is material in the cabinet sufficient for two instruments.

The pillar, L, is placed over the hole, *a*, and the spring, R, is secured to it by means of the bolt, K. The stem, *m*, of the magnet core, D, is secured in the hole, *b*, and the helix, B, placed on the core. The wire, Q, is screwed into the hole, *d*, so that the end touches the top of the spring, R, while the armature, *r*, is a short distance from the core, D. The key, U, is fastened to the bed by a small screw passing through the hole, *t*, into the hole, *h*, in the bed. Under the key a round-headed screw is placed in the hole, *g*, forming a contact point for the key. This screw is connected with the brass clip, *u*, by a wire. One terminal of the coil, B, is connected with the key, U, the other with another similar instrument. The clip, *u*, is connected with the battery,* the ground, or the return wire.

When these instruments are used on a closed circuit, the

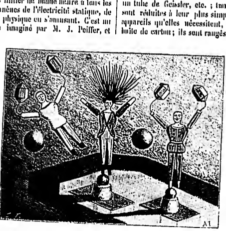
* A suitable battery for this apparatus may be found among those described in SUPPLEMENTS 157, 158, and 159. Perhaps the Tom Thumb will answer as well as any home made battery.

UN JOUET SCIENTIFIQUE

L'ÉLECTROPHORE-PEIFFER.

La Nature 20 Dec 1879

Au moment de l'approche des étrennes, il nous paraît intéressant de signaler à nos lecteurs un charmant petit jouet, qui obtient un très grand succès auprès des enfants, et, qui a le mérite incontestable de les initier de bonne heure à tous les principaux phénomènes de l'électricité statique, de leur apprendre la physique en s'amusant. C'est un petit électrophore imaginé par M. J. Peiffer, et réduit à un tel degré de simplicité, qu'il consiste uniquement en une mince plaque d'ébonite, de 1 millimètre d'épaisseur, et de la grandeur d'une page de *La Nature*. Le disque de bois étamé de l'électrophore classique qui se trouve décrit dans tous les traités de physique, est remplacé par une petite feuille d'étain de la dimension d'une carte à jouer, et collée sur une des faces de la plaque d'ébonite.



Les pantins de sureau de l'électrophore d'ébonite de M. J. Peiffer.

L'électrophore d'ébonite, produit l'électricité avec une remarquable facilité. Vous le posez à plat sur une table de bois, vous le frottez successivement sur ses deux faces avec la main bien ouverte ; si vous le soulevez en le tenant de la main gauche, et si vous approchez la main droite de la feuille d'étain collée sur une de ses faces, vous en ferez jaillir une étincelle de 1 à 2 centimètres de long.

L'électrophore d'ébonite est complété par une série de petits accessoires construits avec beaucoup de goût. Ce sont des petits pantins de sureau, qui permettent de manifester d'une façon très amusante, les phénomènes d'attraction ou de répulsion électriques. Électrisez le plateau d'ébonite, placez sur sa feuille d'étain les trois petits pantins de sureau qui se joignent à l'appareil, soulevez le plateau pour l'isoler de son appui. Voici un petit personnage qui lève les bras vers le ciel, en voici un second, dont les cheveux de soie se hérissent, en voilà un troisième plus léger que les autres qui s'élance comme un clown et qui s'échappe en voltigeant, avec les deux petites balles de sureau qui ont été également placées à côté de lui. Nous avons groupé en une seule figure les trois petits personnages, mais on les fait habituellement fonctionner isolément.

M. Peiffer a réuni dans une boîte, tous les accessoires connus d'une machine électrique : une petite bouteille de Leyde en miniature, un carillon électrique, le pistolet de Volta, le carreau étincelant, un tube de Geissler, etc. ; toutes ces expériences sont réduites à leur plus simple expression et les appareils qu'elles nécessitent, tiennent dans une boîte de carton ; ils sont rangés à côté de l'électrophore d'ébonite qui se trouve ainsi remplacer une machine électrique encombrante et d'un fonctionnement délicat.

M. J. Peiffer complète enfin son petit cabinet portatif de physique électrique par une brochure très substantielle qui sert de guide au jeune physicien et lui enseigne les premières notions de la science.

« Il est facile de comprendre, dit M. Peiffer dans sa préface, combien on peut et combien on doit, pour l'instruction de l'enfant, tirer parti de ses facultés naissantes. Voulez-vous les utiliser fructueusement ? Mettez lui entre les mains, les jouets qui sous une forme attrayante, le familiarisent de bonne heure et sans fatigue avec des sciences dont plus tard la connaissance lui sera absolument indispensable, et cela en l'amusant bien plus qu'avec des joujoux qui depuis si longtemps sont toujours les mêmes. »

Voilà de bonnes et saines paroles auxquelles nous nous associons pleinement. Oui, la science bien comprise, bien enseignée, peut être mise à la portée de l'enfance, elle doit animer les jouets, et servir à la culture des jeunes intelligences, comme plus tard elle contribue à assurer le développement des travaux de l'homme fait.

GASTON TISSANDIER.

---

in two years of 360*l.* 18s. 6d. In addition to the foregoing 49*l.* 16s. 7d. was granted to other trades and unemployed members.

The remaining portion of the expenditure is thus accounted for:

	£	s.	d.
Rent of club rooms and general office, including fuel and gas ...	173	16	6
Salaries:			
Eighty-five branch secretaries, and general secretary ...	407	17	1
Eighty-five branch treasurers	66	18	7
Eighty-five branch sick stewards	68	11	6
Eighty-five branch and other branch officers	116	1	3
Eighty-five branch auditors, and trustees' banking expenses	61	19	5
Printing and stationery, including annual and monthly reports, emblems, &c.	200	6	3
Postage, parcels, telegrams, money orders, deficiency in currency, &c.	107	3	5
Council and committee meetings, delegations, and loss of time ...	217	15	0
Total amount so expended...	1519	11	0

Of this sum 115*l.* 10s. 8d. must be deducted and placed to income account, inasmuch as the sale of reports, &c., realised that sum, which leaves 1401*l.* 0s. 4d. as the total cost of management, or about 14 per cent.

The balance in hand at the end of the year was 13,038*l.* 10s. 4d.; in 1877 it was 16,464*l.* 7s., being a decrease in the year of 2525*l.* 16s. 8d. The amount owing as arrears was 615*l.* 18s. 5d., making the total worth of the society, at the date of the report, 14,554*l.* 6s. 9d.

The income and expenditure of the executive council, although included in the general accounts, are separately given; the former amounted to 809*l.* 17s. 8d., the latter to 820*l.* 6s. Among the disbursements are: General secretary's salary and office assistance, 148*l.* 4s.; rent of office and residence of secretary, coal, gas, rates, &c., 56*l.* 19s. 5d.; council meetings, revision of the laws, deputations, auditing the council's accounts, &c., 86*l.* 0s. 7d.; and superannuation of the late secretary disabled through age and infirmity, 104*l.* The balance was for printing, grants from the benevolent fund, and miscellaneous items, all of which are embraced in the general accounts previously given.

The tables are only made up for 12½ years, dating from 1867. The total income for that period was 96,809*l.* 11s. 5s., the expenditure 89,292*l.* 0s. 3d. The disbursements during the same time have been as follows: Out of work benefit, 26,238*l.* 19s. 5d.; travelling relief, 2078*l.* 18s. 6d; sick benefit, 20,630*l.* 10s. 3d.; accident benefit, 3300*l.*; superannuation, 6201*l.* 11s. 4d.; funeral allowance, 6808*l.* 10s. 10d., making a total of 65,267*l.* 16s. 4d. The cost of strikes is not given, but that it has not been large is proven by the fact that the whole of the balance of expenditure only amounted to 15,836*l.* 10s. 8d., including benevolent grants, salaries, printing, and stationery, postage, grants to other trades, rents of offices and club rooms, strikes, and all incidental expenses for 12½ years.

The average number receiving out of work benefit throughout the year was about 234, the number on the sick list during the year was 910, the number of deaths was 76, and of accidents 5. Consumption again was the fatal enemy as in all the other iron trades.

Some half a dozen pages of the report are devoted to a discussion of the two most prominent topics of the day, depression in trade and foreign competition, but the matter, for the most part, is too general to be quoted. Briefly put, the conclusions drawn may be summed up in two phrases, over-production and over-speculation. The report says: "Striking instances of over-production can be pointed to in the coal, iron, or cotton trade, which may be termed the staple trades of this country." As evidence of over-speculation the active promotion of public companies during the few years following 1871 is referred to, and the enormous prices paid as purchase money, and otherwise, are alleged to have been the true causes of the present slackness in trade. "Only a legitimate and honest system of trading will secure us a return to prosperity," says the report. With reference to the question of foreign competition the following remarks occur: "Our own trade being competed with we do not hear of, only on rare occasions is it uttered, but so far as we can see, hear, read, or learn the nearest approach to competition in engines or machinery is from the American people, for France makes little of that class, and Germany if she does must be subsidised, whilst Belgium is more in the manufacturing of iron itself." Speaking of the alleged importation of cotton goods from America the report says, "The bubble burst when it was found to be an old statement. Ready cash was wanted, and knowing the British failings, they imported here a limited quantity, but the experiment was not repeated."

The report as a whole is interesting and valuable, furnishing as it does an insight into the inner workings of trades societies. It is more full of minute details than the others examined, but the numerous particulars are chiefly interesting to the members themselves. So exact and precise is the information given that every member of the union can be his own auditor.

The following summary of the four great societies in the iron trades may be found useful. Number of branches, 768; number of members, 80,859; income, 217,032*l.* 19s. 11d.; expenditure, 272,545*l.* 18s. 6d.; cash balance, 331,066*l.* 19s. 3d.; arrears due, 21,270*l.* 6s. 0d.; total worth, 354,797*l.* 5s. 10d. Payments made during the year: Out of work, 141,001*l.* 9s. 10d.; benevolent grants, 5390*l.* 3s. 6d.; sick benefit, 56,401*l.* 5s. 11d.; accidents, 5419*l.* 14s.; funerals, 14,560*l.* 3s. 3d.; superannuation, 21,453*l.* 15s. 1d.; grants to other trades, 820*l.* 6s. 7d.; total for benevolent purposes in one year, 225,016*l.* 18s. 2d.; total for strikes, 10,147*l.* 0s. 6d., quite one-half of which was left as a legacy from 1877 arising out of the strike and lock-out on the Clyde.

Engineering 29/8/7

THE BRITISH ASSOCIATION.

In our notice of last week we dealt chiefly with the proceedings of the sections of Thursday the 21st instant, we now continue our notice of the meeting on the next and following days.

The business in Section A commenced on Friday, by Professor W. G. Adams, F.R.S., reading the Report of the Committee for procuring Reports on the Progress of Mathematics and Physics. This was merely a formal report, Professor Adams stating that, in consequence of the serious illness of Professor G. Carey Foster, F.R.S., the committee had been able to hold only one meeting during the year. The report contained two communications to the Committee, the one from Professor Clerk-Maxwell, F.R.S., and the other from Professor Stokes, F.R.S., giving their opinions on the questions with which the Committee has to deal, and the report concluded with the announcement that Professor Stokes had promised to draw up the plan of a Report upon Physical Optics, especially in reference to the Theories of Reflection, of Dispersion, and of Fluorescence and Phosphorescence. The Committee had also to announce that Professor Balfour Stewart had undertaken, in conjunction with J. Allan Broun, to draw up a Report upon Terrestrial Magnetism.

UNDERGROUND TEMPERATURE.

Professor J. D. Everett, F.R.S., next read the twelfth Report of the Committee on Underground Temperature, which was appointed to investigate the laws regulating the temperature of the earth at various depths below its surface, and to find out what is called the "temperature gradient" for various localities, which is the rate of increase of underground temperature as the depth is increased. Various methods of taking underground temperatures are recorded in the report, one of which is the lowering of maximum thermometers into deep bore holes filled with water. Another mode is to take observations in mines and collieries of the readings of very slow-acting thermometers. These instruments are constructed with bulbs of very thick glass so as to be very slow in absorbing heat from surrounding objects, and as slow in parting with it. The object of the thickening of the bulbs is to avoid the reading of the instrument altering to any noticeable extent while it is being drawn to the surface. Sometimes, instead of thick bulbs being employed, ordinary thermometers are used having their bulbs covered with a thick mass of tallow or other substance having a low conducting power for heat. The report goes on to refer to the experiments of Dr. Stapff, made in the St. Gothard Tunnel, in which a mean temperature gradient for the whole length of the tunnel (about nine miles), was found to be 1 deg. Fahr. for every 88 ft., but Dr. Stapff found that where the surface of the upper ground is a steep ridge the temperature gradient is less rapid than that, which is quite consistent with the hypothesis that the earth was at one time very much hotter than it is now, and that it is undergoing a process of cooling down. Experiments had also been made for the Committee by Mr. G. F. Deacon, the engineer to the borough of Liverpool, in a well-boring 24 in. in diameter, being made in connexion with the Liverpool Water Works at Bootle, and the temperature at a depth of 1362 ft. was found to be 59 deg. Fahr.—which is moderate compared with the temperature at the same depth in other localities. Another series of experiments had been conducted by Mr. E. Wethered, of Weston, near Bath, in a colliery in that neighbourhood, and in which the following temperatures were ascertained:

Depth		Temperature Fahr.
at surface	... ...	48.7 deg.
402 ft.	... ...	51.7 "
1232 "	... ...	66.7 "
1367 "	... ...	68.15 "
1439 "	... ...	69.7 "
1769 "	... ...	74.7 "

which figures give a temperature gradient of 1 deg. Fahr. for every 68 ft. Mr. G. J. Symons, taking temperatures in a well at Kentish Town, had experienced a difficulty in consequence of the stretching of the wires by which the thermometers were suspended, the effect of which was to lower the instruments at the rate of from 2 ft. to 14 ft. per month, thereby causing them to descend into warmer strata; but, as the temperature gradient for that locality is known, the correct readings were computed without difficulty. Experiments in connexion with this subject had also been made at a depth of 4500 ft. in the Comstock Lode Mine, in Nevada. At the conclusion of the reading of the report, Mr. G. Johnstone Stoney, who presided on the section, announced that the underground temperature Committee had been reappointed.

ATMOSPHERIC ELECTRICITY.

Dr. Michael Grabham next read a report of his experiments made in the island of Madeira for the Committee on Atmospheric Electricity, in which it appeared that in certain atmospheric conditions, and especially during the prevalence of certain winds, there was no atmospheric electricity that could be detected by the instruments which he employed, while he had found at other times that such electricity was at its maximum from 11.30 A.M. to 2.30 P.M.

Mr. McAlister, in proposing a vote of thanks to Dr. Grabham, stated that he had, from cases coming under his notice in St. Bartholomew's Hospital, observed a connexion between the prevalence of asthma and the frequency of positive atmospheric electricity, and he thought that a consideration of this aspect of the case might be of great importance with respect to the sending of asthmatic patients to Madeira. Professor Atkinson in seconding the vote of thanks referred to the report as a very valuable communication, and expressed the hope that it would be printed *in extenso* in the annual report.

TELEPHONIC PHENOMENA.

The next communication was one by Dr. Silvanus P. Thompson, "On the Retardation of Phase of Vibrations transmitted by the Telephone." In this paper, a full abstract of which we published last week,* the author commenced by a reference to the theoretical prediction of Dubois-Raymond and the more recent experimental demonstration by Koenig, that when two Bell telephones are connected together, the one as a transmitting instrument and the other as a receiver, the vibrations of

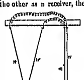


Fig. 1.

the latter take place a certain time after those of the former, which time is equal to that occupied by a quarter of a complete vibration, a retardation equal to that amount taking place in the ultimate transmission. In order to demonstrate this fact the author devised the following experiment. The magnets and coils of two telephones A A, Fig. 1,

le public sans cesse déçu par l'annonce trop souvent répétée de nouveaux progrès dont on n'entend plus parler.

Ce qui n'est pas moins nuisible au développement de la vraie science, c'est la manie trop répandue de déserter prématurément des appareils excellents, mais qui ont le tort irrémédiable, aux yeux de certaines gens, de ne pas être nouveaux, de ne pas avoir été inventés par des Anglais ou des Allemands, et, par-dessus toutes choses, d'être d'une grande simplicité.

Nous sommes heureux de voir qu'une des sommités de la science électrique proteste contre un travers si préjudiciable, et contre lequel nous nous sommes élevés tant de fois.

Nous profiterons de cette occasion pour déclarer de nouveau que les appareils scientifiques et surtout les ~~appareils électriques doivent~~ être créés à l'usage ~~de la~~ nature qu'ils sont appelés à étudier. Le *Ne quid nimis* du poëte doit s'y appliquer de la façon la plus rigoureuse.

Les savants qui accumulent formules sur formules et bobine sur électro-aimant rencontrent rarement la vérité, qui n'aime pas à sortir de son puits si grotesquement affublée.

Electricité

L'ÉLECTRICITÉ A L'EXPOSITION DE BERLIN

1 — 5 July 1879

Si l'on voulait avoir une idée approchée de l'état de l'électricité à l'Exposition de Berlin, il suffirait de décrire l'exposition de la maison Siemens, dont nos lecteurs connaissent la majeure partie, malgré l'abstention mémorable de l'empire allemand. En effet, la maison Siemens, de Londres, qui nous avait envoyé une collection si nombreuse d'objets de toute nature, n'est guère moins importante que celle de Berlin. C'est même dans ses ateliers, à Woolwich, que l'on construit en ce moment le câble transatlantique français (1).

Dans l'exposition de M. Siemens à l'Exposition de Berlin se trouvent un grand nombre d'objets plus ou moins analogues à ceux qui ont figuré à l'Exposition du Champ-de-Mars, et sur lesquels il n'y a pas, par conséquent, lieu de donner de nouvelles explications à nos lecteurs. Nous devons cependant noter l'*unité de résistance*, qui, comme on le sait, est une colonne de mercure d'un millimètre de section et d'un mètre de longueur. En effet, cette unité est certainement la plus facile à reproduire rigoureusement. A cause de sa grande facilité à distiller, le mercure est de toutes les substances métalliques celle qui peut le plus facilement être obtenue à l'état de pureté absolue. En outre, sa fluidité et sa conductibilité propres lui permettent de recevoir la température ambiante d'une façon très-uniforme et très-rapide. Cette unité de résistance est donc bien préférable à toutes les autres.

(1) La maison Siemens a établi une succursale à Paris, une à Saint-Pétersbourg et une autre à Tiflis. L'établissement de Paris et de Saint-Pétersbourg sont plus particulièrement consacrés aux machines à lumière, et l'établissement de Tiflis à la métallurgie du cuivre et du cobalt. Une autre succursale a été également établie à Charlottenbourg.

NOUVEAU PENDULE ÉLECTRIQUE

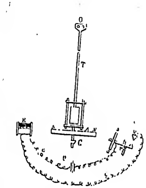
Electricité 20 July 1879

Parmi les applications nouvelles de l'électricité, il en est une très-intéressante, qui a été imaginée par M. V. de Sauty, électricien de l'Eastern Telegraph Company, à Gibraltar, et qui consiste à entretenir électriquement le mouvement d'un pendule battant la seconde. Sauf le point de suspension, il n'y a aucune espèce de contact, ce qui a l'avantage de supprimer les frottements; la construction d'ailleurs en est très-simple. Le dessin ci-contre représente la disposition des différentes pièces.

La tige du pendule, T, fixée en O, à l'aide d'une lame-ressort, porte à sa partie inférieure une lentille B, pouvant contenir une petite quantité de mercure et une vis curseur C, facilitant le réglage. A est un aimant aplati, ayant environ 18 centimètres de longueur; les pôles sont représentés par N et S.

E est un électro-aimant ordinaire, dont les hélices magnétisantes sont formées de fils en cuivre recouvert de soie, n° 36, et présentent une résistance électrique de 320 unités Ohms (environ 32 kilomètres de fil télégraphique de 4 m/m de diamètre). Le petit aimant *a*, mobile sur un axe, porte au bras de levier *b*, qui peut venir s'appuyer sur une vis butoir *v*; le ressort *r* le ramène sur la vis inférieure, formant arrêt. *c*, *c* indique le circuit comprenant deux éléments Minotto, l'électro-aimant, l'axe de l'aimant *a*, et la vis butoir *v*.

Lorsque le pendule oscille à droite, l'aimant A attire le pôle de nom contraire de *a*, et celui-ci, tournant sur son axe, ferme le circuit de la pile. Le courant circule dans l'électro aimant, de façon à déterminer une polarité convenable et les noyaux de fer doux, et le pendule attiré oscille vers la gauche. Le circuit reste fermé jusqu'à ce que la tige atteigne la verticale, ce qu'on obtient facilement par le réglage de l'aimant *a*. En ce point, aucune force attractive n'agit sur l'aimant, et le pendule, en vertu de la vitesse acquise, achève son oscillation, puis revient à droite pour attirer de nouveau le petit aimant.



117

Pour éviter autant que possible l'influence des perturbations magnétiques, il convient de placer l'aimant principal dans le plan du méridien magnétique. Le fil de l'électro-aimant pourrait être plus gros, mais on comprendra facilement qu'en augmentant la résistance du circuit, les variations du courant, qui se produisent infailliblement, auront moins d'action, et par suite la force attractive restera sensiblement constante.

D'après M. de Sauty, ce pendule fonctionne régulièrement depuis le mois de novembre dernier avec deux éléments, et il pourrait servir à la transmission électrique de l'heure à distance.

MAITRE JEAN.

[37809.]—Electric Vibrating Beam.—Presuming that the beam is balanced, if you decrease the force employed to make it vibrate, you will decrease the velocity of its motion; consequently, it will make fewer vibrations per second. If you are using an electro-magnet and counteracting spring applied to one arm of the beam, remove the magnet a little further from its armature and decrease the tension on the spring, to suit the decreased attraction of the magnet; or perhaps you could make the beam longer, when it would vibrate more slowly. If neither plan will do send further details of the apparatus, and say what it is for. J. BROWN, Belfast. Eng Mechanic Sep 12 1879

ELECTRICITY & TELEGRAPHY

Electro-Magnetic Stopping-Motion for Spinning Frames.—In the Augsburger Kammgarnspinnerei there is now working an ingenious contrivance, in which a current of electricity is employed to effect the stopping of the spinning frames. The apparatus consists of an arrangement for closing an electric circuit, in connection with special mechanism attached to the driving power of the frame, and which, upon the breaking or failing of a thread, either on entering or leaving the frame, automatically stops the latter. The stopping-motion consists of an arrangement of disengaging-gear, acting directly on the driving-band of the frame; of a series of thread-guides which act as circuit-closers at the entrance of the yarn into the frame, with similar guides or circuit-closers at the issue of the doubled yarn, before it is wound on the spools; and of a brake for the immediate stopping of the frame.—*Electrician.*

Military Telegraphy in Austria.—Since 1873 the regiment of Pioneers has been charged with the duty of training and providing men who will form special railway and telegraph detachments. So long as the army is on the peace footing the men who are destined to form the telegraph detachments remain attached to their respective battalions of the Pioneer regiment. They are trained and exercised in all the ordinary duties of the pioneer soldier, and once a year they have a course of special training and exercise in field telegraphy. In case of war all these specially-trained men can be withdrawn from the Pioneer service and formed into a special corps. Each Pioneer battalion is required to be able to furnish eleven telegraph detachments. This would give a total of fifty-five detachments, who with their *matériel* and appliances would at once constitute a telegraph network 119 (440 English) miles long and embracing 220 stations. The yearly exercise of the detachments stationed in the neighbourhood of Vienna was held at the close of last month. The headquarters were fixed in the Prater, where a quantity of reserve materials was collected. The strength of the detachment consisted of four field telegraph officials, who must be ready to act both as operators and clerks, one superintendent, twenty-three artificers of all kinds (from mere field labourers for setting up the poles to men competent to repair machinery), two wagons to serve as stations, and four wagons for the transport of materials. The station wagons resemble a wooden house; they are divided into compartments and thoroughly fitted up for the reception of the instruments, &c. Two complete sets of instruments and other necessary furniture are allotted for each station, so as to be as independent as possible of accidents, and an abundant supply of stationery, &c. The wagons for materials contain two (eight English) miles of copper wire, and a corresponding quantity of telegraph cable to be employed in marshy places or in crossing rivers, and a sufficient number of poles for supporting the wire at average distances of fifty paces. These poles are to be long enough to allow of the wire being carried at an average height of four metres (about 13 ft.) above the ground.

Electricity and Heat.—In a series of experiments recently described to the Vienna Academy, Prof. von Waltenhofen has sought to deduce from a direct measurement of the work done in induction of an electric current in a closed circuit of given resistance, the mechanical equivalent of heat. For induction, a magneto-electric machine was used, whose electromotive force was ascertained to be proportional to the number of revolutions. A dynamometric handle of the newest construction was attached, and it was furnished with an arrangement for receiving the work-diagrams. The induced currents were measured by means of a tangent galvanometer. The results were found to be in satisfactory agreement with Joule's equivalent.

AN IMPROVEMENT IN THE SIEMENS ARMATURE.

Electrician July 17 1880

When we get the dynamic diagram of a Siemens bobbin, by making it operate through an entire revolution between the two poles of the electro-magnets which act upon it, we see that the work is almost *nil* during two considerable portions of the rotation. These two periods correspond to the times during which the cylindrical poles of the bobbin, having attained the poles of the magnet, defile before them. During these two fractions of a revolution, which are each about 30°, the magnetic surfaces destined to react upon each other, remain at the same distance. The bobbin is not then urged to turn, when it is being driven by the transmitted current from a second machine, and the result is a notable loss of work done.

These indifferent periods have, however, been suppressed by M. G. Trouvé, the well-known French electrician, and the usefulness of the machine thereby much improved. This has been effected by modifying the bobbin in the following manner:—The polar faces, instead of being portions of a cylinder of which the axis coincides with that of the system, are in the form of a *limaçon* or "snail," so that in turning they approach gradually their surfaces to those of the magnet until the moment when the posterior edge escapes from the pole. The action of repulsion then commences, so that a "dead point" is practically avoided.

The importance of this improvement has been shown by a very simple experiment. Two Siemens bobbins of the same diameter have been constructed, of the same length and wind, one only being modified in the way described. These have been successively tested by substituting them for one another in an electric motor, and it has been proved that with the same battery power the modified bobbin gives a considerable increase of work over the other.

The bobbin can act in presence of a permanent magnet, but M. Trouvé prefers to employ as a fixed magnetic reacter an electro-magnet placed in the same circuit, which permits the energy of the current to be varied between far-apart limits without the respective magnetic intensities of the fixed and movable organs ceasing to exist in the relation desired.

At a recent meeting of the French Academy M. Trouvé exhibited a small motor constructed upon this principle, and a single cell of Regnier's battery (described in our issue for July 10) put it into rapid rotation and drove a sewing machine; in fact, the instrument with the cell formed a promising little household motor; moreover, it is reversible in its action, and can be made a generator of electricity.

ELECTRIC JEWELRY.

Among the specialties for which the French are noted there is nothing more curious than the electric jewelry, several specimens of which are shown in the accompanying cuts, which we take from *La Nature*.

The scarf pin represented in the left-hand figure consists of a small golden rabbit holding a lilliputian mallet in each paw, with which it beats a roll on a small golden gong. The right-hand figure represents a golden skull, with movable diamond eyes and an articulated jaw. This is also a scarf pin, and its eyes and jaw are made to move in a singular manner. The bird shown in the center of the engraving is an ornament for the head dress. It is of gold, thickly studded with diamonds.

These pieces are connected by a fine concealed wire with a small battery carried in the vest pocket. When the battery is made to operate, the rabbit will strike the gong, the bird will move its wings, and the skull will roll its eyes and gnash its teeth.

The battery consists of a zinc and carbon couple contained in a hermetically closed vulcanite case, the zinc and carbon occupying the upper half of and the exciting fluid the lower half of the case. When the case is in a vertical position the exciting fluid does not touch the zinc or carbon, but when it is inverted or placed horizontally, the fluid comes into contact with the zinc and carbon, and the current traverses the coils of the diminutive magnets, which operate the mechanism of the pieces. The arrangement of the internal parts of both battery and scarf pin will be understood by reference to Fig. 2. The mechanism is much like that of an ordinary vibratory electrical bell.

ELECTRICITY & TELEGRAPHY

From Feb 20 1879

THE NEW CAPE CABLE.—Information reached the officers of the Eastern Telegraph Company, on Wednesday, that the steamship *Seine* had arrived at Aden, having laid down the section of the new Cape cable between Mozambique and Delagoa Bay, which thus far completes the line of telegraphic communication from Natal to Mozambique. It is believed that the other section from Mozambique to Zanzibar will be finished by the 20th inst., and South Africa thus brought into direct communication with Zanzibar. From there it will take about nine days to bring news by ship from South Africa. In the course of time the entire route is to be completed.

CABLE BETWEEN ALGERIA AND FRANCE.—The first section of the cable which is to connect Algeria and Marseilles has been laid with perfect success, and the immersion of the remainder of the cable is being proceeded with. The Governor-General of Algiers, accompanied by several generals and civil officials, paid a visit to the steamer *Dacia*, which is engaged in the work of laying the cable, and partook of a lunch offered to them by the captain and officers of the vessel, during which toasts were drunk to the health of her Majesty the Queen and the President of the French Republic.

THE ELECTRIC LIGHT AT ST. ENOCH STATION, GLASGOW.—On Tuesday night the Glasgow and South-Western Railway Company tested the electric light as a means of illuminating their magnificent station at St. Enoch Square, Glasgow, with a view to adopting this mode permanently if found to work satisfactorily. Four lights were used, doing away with 460 gas-burners, and giving four times the illuminating power. The effect was very fine, the whole of the station being flooded by the brilliant light. Mr. Joshua Horton, agent for the British Electric Light Company, had charge of the arrangements, and was in attendance on Tuesday night to give explanations as to the working of the system. The cost of the four lamps will be about 1s. 4d. per hour, and the light afforded is equal to that given by 24,000 standard candles.

TELEPHONES IN HOSPITALS.—The use of telephonic communication is gradually being extended, and, although we have not yet obtained telephonic exchanges for commercial purposes, the system is becoming more and more popular. Quite recently, the Children's Hospital at Pendlebury, near Manchester, has been fitted with a system of telephones. The lady-superintendent's room is thus connected with each of the six wards, the kitchen, and the pantry. As the hospital consists of six pavilions opening into a long corridor, the most distant pavilion being about 120 yards from the administrative block, it is obvious that much time and labour in running to and fro are saved by this convenient method of communication. It is especially convenient in communicating with the fever ward thus avoiding the risk of conveying infection to other parts of the hospital. The instruments were the gift of Mr. W. P. Henderson, jun., and Mr. E. P. Dewhurst, of Manchester. They are in constant use, and give great satisfaction.—*The Electrician.*

THE ELECTRIC LIGHT AT A DISTANCE.—An interesting experiment to test the extent of the illuminating powers of the Maxim electric light was recently made one evening at Saratoga Springs, New York. The light was put in operation on the tower of the Grand Union Hotel. An open parabolic reflector was used—no lenses—and care was taken by Mr. Maxim to set the points of the carbons a little on one side of each other and to adjust them exactly to the focus of the reflector. This having been accomplished, the light was turned towards a spot in Ballston Spa, New York, 7½ miles distant, where, by previous arrangement, a group of several hundred persons were assembled to witness the experiment. The place was instantly illuminated in such a way that ordinary printing could be read, the time seen on watches, &c. The night was clear, still, and dark. The experiment was made at 9·30 p.m. This is believed to be the greatest distance at which illumination of equal degree has been accomplished.

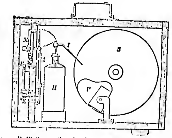
ELECTRICITY APPLIED TO BEE-REARING.—A Correspondent of the *Deutsche Presse* describes a method which he has adopted with success of overcoming the obstacles frequently presented to the rearer of bees by the self-will of those interesting and profitable insects. This is no other than giving them an electric shock. Every one interested in bees knows the difficulties and dangers involved in hiving a swarm. One is often seen on a hot day in June in the top branches of a tree not to be climbed, and another in some inaccessible place seems to be preparing to set out on its wanderings. If the beemaster venture to approach, all his dexterity and experience will often not prevent him from being seriously stung. There are, indeed, several cases on record of death supervening from the stings inflicted on such occasions. Herr Freiwith, the correspondent referred to, hit upon the idea of employing the electric force to stupefy the bees. Trials on large and small clusters, and even on single insects, answered perfectly; the bees coming in contact with the conducting wires felled stunned and motionless to the ground. They were then sorted and marked, according to the strength of the current applied. The time required for their recovery varying from ten minutes to eight hours, was proportionate to the strength of the shock, but all came out of their trance safe and sound. Encouraged by the result of this experiment, Herr Freiwith resolved to try it on a larger scale, namely, on bees in the hive. To this end he introduced the ends of two conducting wires into a fully occupied honeycomb, and turned on the current for a moment; the bees soon lay on the ground, and it was half an hour before they resumed activity. Herr Freiwith then constructed an apparatus in a small box, 6 inches each way, which, similar to a cartridge pouch, he wore with a strap round his body. The two wires of the apparatus were, when required to be used, fastened to rods of a suitable length, the wires of course always projecting over the ends of the rods. These ends were then applied to the swarm, a knob similar to that employed for a room-telegraph being attached to the apparatus, that the current might be turned on at the proper time. Every one is, of course, not skilful enough to construct such an apparatus, though none are precluded from doing so, as Herr Freiwith has not patented it.

Journal of the Telegraph, Aug. 1881.

Appareil électrique à inflammation.

Electricité Sept 1879

Beaucoup de praticiens, même intelligents, ont le tort immense de supposer qu'il est nécessaire d'employer l'électricité dynamique pour tous les grands effets de l'industrie moderne. Il n'est point hors de propos de montrer que l'électricité de friction peut être utilement employée dans beaucoup de cas et que les travaux des anciens électriciens, ces pères d'une science si belle et si progressive, n'ont pas été mis hors de service par les progrès les plus merveilleux que l'histoire ait à enregistrer. Le mode le plus commode de donner le feu aux fourneaux de mine dans lesquels on emploie la dynamite Nobel est exploité par M. Vian, 12, rue Condorcet. Cet appareil se compose de deux disques en résine, auxquels on donne un mouvement de rotation à l'aide d'une manivelle. Ces disques S, dans leur mouvement de rotation, frottent entre des tampons ou coussinets revêtus d'une peau de chat.



Appareil d'inflammation des fourneaux de mine sans tube et par friction.

L'électricité, ainsi développée, s'écoule par la pointe I qui communique avec l'intérieur d'une bouteille de Leyde servant de condensateur. L'armature extérieure H de la bouteille est en communication avec la pointe située à une distance quelconque où se produit l'étincelle. Mais une difficulté se présente dans l'emploi de cet appareil:

Presque jamais, la décharge qui se produit n'est complète, il reste, sur les deux surfaces de la bouteille de Leyde, ce que l'on nomme une charge résiduelle. La partie placée à gauche de la figure compose le déchargeur, dont le jeu consiste à faire éclater une étincelle entre la partie métallique H et la partie métallique M. Ce résultat s'obtient en poussant sur le bouton K, de telle manière que le levier mobile qui termine la partie A vienne toucher le bouton de la bouteille de Leyde.

An Electrical Speech Recorder.

A curious piece of apparatus, not likely to be of practical use, but showing considerable ingenuity, has been devised by M. Amedeo Gentilli, of Leipsic, for the purpose of giving an intelligible record of speech. The natural movements of the mouth in speaking are employed to produce through delicate levers a series of electric contacts, and thereby sundry combinations of signs on a moving band of paper, similar to those of the Morse alphabet. The transmitting portion of the apparatus is based on a careful study of the motion of lips and tongue in speaking with an object held between the teeth. The working parts are mainly arranged on an ebonite plate, from one end of which projects a piece to be taken between the teeth, whereupon the mouth-levers come into position. The nasal puff in sounding *m* and *n* affects a special delicate organ. There are eight electro-magnets in the receiver, each of which, when actuated by a current, causes a line to be formed on the paper. It is mentioned by M. Gueroult (who describes the apparatus in *La Lumière Electrique*) that the letters *g* and *k*, *d* and *t*, *b* and *p*, *f*, *v* and *w*, which are produced by movements very slightly different, are represented by the same signs. Thus of those letters the alphabet comprises only *g*, *t*, *b*, and *f*. Further, *c*, *s*, and *z* are represented by *ts* and *ys*. The apparatus will, perhaps, be shown at the forthcoming exhibition in Paris.

La Correspondance 2 avril 1876

L'HYGIÈNE ET L'ÉLECTRICITÉ

Dans l'une de ses dernières causeries scientifiques, le spirituel chroniqueur du *Temps* M. Lereboulet, rapporte les curieuses observations d'un ancien capitaine amputé d'une jambe. Ce personnage a eu la patience de marquer les heures pendant lesquelles il souffrait du membre qui lui manquait, et de comparer la coïncidence qui existait entre l'époque de ses douleurs et la manifestation des orages, troubles atmosphériques, tempêtes, tous renseignements fournis par le Bureau météorologique central des Etats-Unis (Signal). Il a constaté ainsi que ses souffrances étaient plus accentuées lorsque la pluie approchait que lorsqu'elle tombait, pouvant ainsi prévoir et connaître l'arrivée d'une averse tombant à quelques kilomètres de sa résidence. Bien entendu il ne pouvait dire si la pluie atteindrait sa station, ou si elle passerait au large, mais cette approche de la pluie n'échappait pas à la sensation particulière qu'il éprouvait dans cette jambe privée par le fait de toute innervation réelle.

Quelque bizarre que puisse paraître l'idée du capitaine américain, je crois devoir rappeler ici des observations que j'ai faites moi-même sur une femme déjà âgée, foudroyée dans sa jeunesse, et qui est affectée depuis lors d'un torticolis dont aucun traitement médical n'a triomphé.

Chaque fois que la pluie est imminente, elle éprouve des douleurs assez vives qui ne se calment que lorsque l'averse est tombée. Il serait à désirer qu'on pût noter avec soin les impressions de cette femme, en les comparant avec les phénomènes atmosphériques du moment; mais nos observatoires français ne sont pas assez bien organisés pour permettre la vérification scientifique de faits de ce genre.

Le critique du *Temps* croit émettre un spirituel paradoxe en conseillant aux directeurs des bureaux météorologiques de s'adjoindre pour leurs prévisions, un détachement de vieux mutilés. Il pense même que ces établissements scientifiques seraient fort heureusement placés au voisinage d'un hospice ou d'un hôtel des invalides!

Toujours est-il qu'il est très logique de supposer que l'arrivée des pluies produise des courants électriques, dont les organismes exceptionnellement sensibles, par suite de lésions internes ou de dispositions morbides, ressentent malheureusement la présence par des douleurs très vives et très variées.

N'a-t-on pas constaté depuis longtemps que l'atmosphère n'est parcourue par des courants électriques qu'au moment où la foudre éclate dans le voisinage de nos demeures? Alors, en effet les personnes les mieux portantes ressentent des commotions dont elles ne sauraient ignorer la nature.

Il n'est pas surprenant que les personnes malades ou souffreteuses éprouvent des effets analogues, alors que les courants naturels de l'électricité atmosphérique n'agissent pas sur l'individu bien portant.

Les belles expériences de M. Palmieri ne nous montrent-elles pas que l'atmosphère est parcourue par des courants électriques, alors qu'il n'y a pas d'orage proprement dit à l'horizon, alors que l'on pourrait supposer que l'électricité naturelle est en plein repos.

Trente années d'observations consécutives lui ont démontré qu'aucune pluie ne peut s'approcher de son ermitage du Vésuve sans que l'électroscope n'en décèle immédiatement la présence; et les nerfs affaiblis de personnes maladives ne sont-ils pas des électroscopes plus sensibles que les appareils du savant météorologistes?

Personne n'ignore que les indications fournies par les sens dépassent en délicatesse les instruments les plus sensibles:

Le sens du goût révèle, sans aucune espèce d'hésitation, des traces d'acide sulfurique qui échappent à l'analyse spectrale elle-même.

La membrane olfactive de l'homme est douée de la perspicacité presque magique, de reconnaître le musc renfermé dans une molécule d'air.

Les considérations qui précèdent, et d'autres qu'il serait facile d'énumérer, démontrent l'utilité que le Bureau de météorologie pourrait tirer de pareils auxiliaires.

Examinons actuellement les moyens à employer pour garantir ces infortunés névrosiques contre les souffrances qui troublent si cruellement leur vie.

En les plaçant dans l'intérieur d'une chambre complètement garantie contre les mouvements de l'électricité, comme la célèbre cage de Faraday, par exemple, ne serait-on pas à même de faire cesser les névralgies, les névroses, et autres troubles morbides sous la dépendance du fluide électrique?

De pareilles expériences présenteraient un grand intérêt, surtout si elles étaient accompagnées d'observations recueillies dans un district ou périmètre d'une certaine étendue, et si la chute de toutes les quantités de pluie pouvait être enregistrée avec soin et précision.

Cette étude, aussi intéressante pour la physiologie que pour la médecine, aurait été possible à Paris si l'on avait adopté la création des observatoires municipaux, succursales de l'observatoire central de Montsouris.

Effectivement, si l'on parvient à constater que les mouvements de l'électricité atmosphérique agissent d'une façon si puissante sur l'organisme malade, il sera difficile de ne pas reconnaître entre le fluide électrique et l'influx nerveux une analogie plus intime qu'on ne le suppose ordinairement.

Si l'on ne trouve aucune différence, il faudra de toute nécessité chercher dans d'autres causes efficientes l'origine des susdites souffrances!

Jusqu'à preuve du contraire, nous considérerons l'organisme comme une source d'électricité, en même temps que de chaleur, et dans cet ordre d'idées, nous conseillerons de protéger les malades non-seulement contre les variations de la température, mais encore contre celles de l'état électrique.

Les courants continus, soit directs, soit inverses, ne paraissent agir que faiblement sur l'organisme tant qu'ils conservent une même intensité; c'est lorsqu'ils commencent ou s'interrompent, lorsqu'ils augmentent ou diminuent, qu'ils produisent les mouvements des muscles de la grenouille, qui, avec quelque soin qu'elle ait été préparée, ne saurait acquérir la sensibilité de l'être humain dont le système nerveux est ébranlé.

Or, lorsque l'électrisation de l'air varie, il faut de toute nécessité que l'état électrique de l'individu soumis à ces changements d'influence soit modifié, car on ne saurait admettre que son épiderme possède une puissance isolante assez marquée pour le soustraire aux perturbations du milieu ambiant.

Comment ces modifications pourraient-elles se produire sans que des courants, plus ou moins intenses, ne parcourent en ce moment les fils télégraphiques de la motilité et de la sensibilité?

Qui sait si ces courants spontanés ne sont pas assez énergiques pour engendrer des effets analogues à ceux des courants voltaïques qui, on le sait, donnent lieu à des sensations acides quand ils parcourent les nerfs linguaux, à des bruits quand on les fait agir sur les nerfs acoustiques, enfin à des phosphorescences quand ils cessent d'exciter les nerfs de la vision?

Nous appelons volontiers sur ces faits l'étude et le contrôle de l'observation clinique.

Wilfrid de Fonvielle.

(*Le Journal d'hygiène.*)

ELECTRIC TIME-BALL APPARATUS FOR INDIA.

Oct 31.1879 [illegible]

A VERY complete set of electrical time-ball apparatus has recently been manufactured for the Indian Government, and will in due course be erected at Fort William, Calcutta. The apparatus has been designed by Mr. S. Alfred Varley, whose name is well known in connection with this and similar electrical apparatus, and it has been manufactured at the works of Messrs. Siebe and Gorman, Mason Street, Westminster Bridge Road, where we recently had an opportunity of inspecting its working. The apparatus includes a time-ball, a clock or regulator for giving the time, a commutator for closing the electric circuits, an electric lock, on which the ball hangs until the moment of discharge, and an apparatus for firing a time-gun. The ball, which is 5 feet 6 inches in diameter, and weighs with its attachments about 5 cwt., is wound up a mast by means of a rack and pinion, and falls, when released, through a space of 10 feet. A rod, furnished with a piston at its lower end, is attached to the ball, and after the latter has fallen through a space of 4 feet, the piston enters a pneumatic cylinder, producing a cushion of compressed air, which arrests the descent of the ball without any shock or concussion being experienced. This ball, as regards the size and the space through which it falls, is similar to those which were erected at Charing Cross and Liverpool in 1853 and 1854, at the suggestion of the Astronomer Royal, to whom we are indebted for the idea of utilising electricity for discharging time-balls. Improvements have, however, been effected by Mr. Varley in connection with the pneumatic cylinder, as well as in the discharging apparatus. In the former a pressure-relieving valve has been introduced, which, by preventing any rebound on the part of the ball, gives greater distinctness to the signal. In the latter, greater rapidity and certainty of action are secured by the special mechanical and electrical arrangements we are about to describe.

There are certain dangers to be guarded against in time-ball apparatus, and it is clearly very important that time-signals should be absolutely reliable. The only way to ensure correctness in the working of the time-signal is that the arrangements be such as shall enable the operator at the Observatory, whence the time emanates, to see what is taking place at the time-signal station. This result is obtained by making the time-ball send back a return signal at the moment of its release. The actual force of the electric current employed is very small, whilst the weight of the ball and its attachments, is considerable; the discharge is therefore effected by constructing the lock by which the ball is retained and released of a series of levers, the lightest of which is set in action by the electric current. A greater or less time is occupied by these levers in falling, and the loss due to this cause is, in many of the electric locks, very appreciable; in the Liverpool lock, which was more active in its action than some which have been constructed at a later date, the loss of time amounted to 3-10ths second. In the present apparatus the loss of time due to this cause is only 1-20th of a second. An interval of a few minutes elapses after the ball has been wound up, before the time-signal is sent, during which time the ball is resting upon the electric lock, and there is the danger of the lock being discharged by a false current, before the proper current arrives; such false current may be caused either from the time-wire being accidentally in contact with another circuit, or from meteorological causes.

The greatest possible reliability in the working of the Fort William apparatus is attained in the following way: In the first place, the electric lock is constructed on the polarised system, *i.e.*, to work with opposite electrical currents, the current of one direction more securely locking it, and the current of the opposite direction releasing the lock. The time-ball is discharged at 1 p.m. daily, and the locking current is sent some few minutes before. The discharging apparatus therefore remains firmly locked by an electrical current more powerful than any accidental current is likely to be, until the very moment of discharge. In the next place, the release of the electrical lock divides the electrical circuit, and sends back a return signal, just after the ball has commenced to fall. The attendant at the observatory whence the time is sent sees the interval which elapses between the sending of the time-current and the receiving the return signal, recording the fall of the ball. It is, therefore, made clear to him that the current has done its work efficiently. Again, the loss of time in the lock itself has been reduced to 1-20 second, as before stated, and should any hanging fire occur in the electric lock, it is indicated both at the sending and at the time-ball stations. The gun is fired by means of an induction coil and a local battery, which is set in action by the time-current. In connection with this apparatus, there is also an electric lock, which prevents the gun being put in circuit until it is protected from any false current by the preparatory signal, which remains from a few minutes before 1 p.m. until the moment of discharge. The first time-ball apparatus constructed on the polarized system was designed by Mr. S. A. Varley, at the instance of the late Sir Thomas Maclear, Astronomer Royal at the Cape of Good Hope, for the Port Elizabeth time-ball, which was inaugurated in August, 1865, and gives time to the shipping in Algoa Bay. This ball is discharged from the Cape Town Observatory, which is distant 500 miles, and the return signal, recording the falling of the ball, was stated by Sir Thomas Maclear to have been received 1-15th of a second after the time-current was sent. The time-ball over Messrs. Dent's, at Charing Cross, and which has been daily discharged by Greenwich current for the last six years, is also constructed on the polarized system, but only one current is used, and no return signal has been provided for, as it is not deemed necessary. The apparatus we have been describing was inspected on Tuesday last by General Hyde and Mr. W. F. Batho, C.E., on behalf of the Indian Government. Its working was found to be perfectly satisfactory, and it will shortly leave the manufacturers' works for its destination.

LE DRESSAGE DES CHEVAUX

PAR L'ÉLECTRICITÉ

MORS ET STICK ÉLECTRIQUES.

On a souvent proposé des moyens divers pour arrêter et maîtriser les chevaux emportés ou rétifs, il n'en est pas de plus ingénieux et de plus efficace que celui qui a été imaginé par M. Defoy et dont M. Bella, administrateur de la Compagnie des Omnibus, a récemment apprécié les avantages devant la Société d'encouragement[1].

M. Defoy exécute chaque jour de remarquables expériences que nous croyons devoir signaler à nos lecteurs. Disons d'abord en quoi consiste le système employé. C'est simplement un petit appareil de Clark renfermé dans une boîte qui peut facilement être placée sous la main du cocher ou du cavalier. Les rennes du cheval contiennent intérieurement un fil métallique conducteur qui aboutit au mors d'une part, et à l'appareil magnéto-électrique d'autre part. En tournant la manivelle de l'électro-aimant, on détermine la formation d'un courant électrique qui agit dans la bouche du cheval, et lui cause une telle surprise qu'il s'arrête et reste immobile. En joignant à l'action de l'électricité la douceur et

Cheval lancé au galop, instantanément arrêté par l'action d'un mors électrique. (D'après nature.)

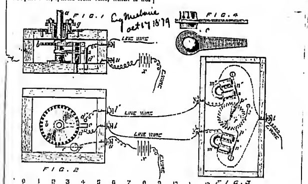
les caresses, le cheval le plus dangereux est rapidement maîtrisé.

M. Bella rapporte que M. Defoy a expérimenté son appareil sous ses yeux, au dépôt de la Compagnie générale des Omnibus, où se trouvent réunis les chevaux les plus méchants et les plus dangereux. Un cheval hongre très difficile à ferrer fut amené à la forge où il se montra extrêmement méchant, on le munit de la guide conductrice du courant : au bout de quelques minutes d'expérimentation, le cheval se laissa caresser l'encolure et le dos, puis toucher les jambes, et finalement relever les pieds de derrière, toujours les plus difficiles à aborder et à relever. « On frappa sur le fer sans qu'il se révoltât, dit M. Bella, et on lui changea ses fers, sans qu'il fût entravé et sans qu'il recommençât ses dangereuses défenses. »

Le directeur de la Compagnie parisienne des Petites Voitures a récemment aussi constaté l'efficacité de ce procédé. « L'expérimentation, dit M. Camille, dans un rapport que nous avons sous les yeux, a eu lieu sur plusieurs chevaux qu'il avait été jusqu'alors impossible de ferrer, tous sans exception ont cédé à l'influence de l'appareil. Un cheval qu'il s'agissait de ferrer allait jusqu'à se rouler à terre, se débattant, se défendant et luttant contre tout, rien ne pouvait le dompter. J'eus recours à l'appareil de M. Defoy; à la première expérience, au levé, à mon grand étonnement, sans de grandes difficultés,

[1] *Société d'Encouragement*, séance du 25 avril 1879.

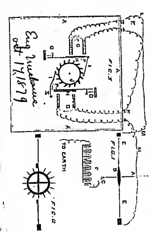
[38216.]—Electric Vane.—If the editor can understand my rough sketch to engrave it, I think "F. W. W." will see my plan of trying to do what he requires. A, spindle from vane, which is not



Eng Mechanic oct 17 1879

shown; B is a wheel soldered to spindle; the wheel will require say 16 projections (as in sketch), tipped inside with platinum, as shown at Fig. 2, so that as it revolves the projections will come in contact with two steel springs, E, E, which at their ends must be tipped with platinum on, say, front side and ebony the other; the spindle, A, terminates in a small cup of mercury, C, which is connected to one pole of battery F, the other pole is connected to earth, therefore if the wheel B is turned to the left a current will be sent through the left spring, E; if turned in the opposite way the current will travel through the other spring, as the contact will be broken on the left side by the tip of ebony on side of springs. Two line wires, M, M, will have to be connected to springs, E, E, and carried to where the indicator is fixed. Fig. 3, inside of indicator; the front of it and pointer are not shown; K, K, are binding screws, line wires to be connected to one of them on each side; G, G, magnets; H, armature; O, screws for regulating springs; P, are studs to keep armatures from springing too far back; I, I, are ratchets fixed with a pivot on the top of armatures; the lower one will require a spring, as shown at S, to prevent it from falling from the wheel, J, which must have same number of cogs as the wheel B (Fig. 1) has projections; on the spindle of the wheel J is fixed the pointer. The action is as follows: Suppose the vane turns the wheel B to the right, a current is sent through the magnet on the right side, which draws its armature forward and turns the wheel J and pointer one notch every time the projections on wheel B come in contact with spring E; when turned back it causes the current to be sent through the other magnet, which will work the wheel J and pointer in the opposite direction; the circuit is completed by the wires L being connected to earth. By having 32 projections on wheel B and same number of cogs on J, the indicator should show all points of the compass. What is Mr. Lancaster's opinion of the arrangement?—G. T. Bunsnell.

[38216.]—Electric Vane.—In reply to "F. W. W.," I send drawing of a piece of apparatus which I designed for this purpose some years ago. It is still in a crude form, and needs working out as regards details, but it may give "F. W. W." an idea. Fig. 1 is a sectional elevation of the transmitter; Fig. 2 a sectional plan of ditto; Fig. 3 plan showing interior of receiving instrument or indicating dial; Fig. 4 an enlarged view of the arm c in Figs. 1 and 2. a is the spindle of weathercock, the movements of which are to be transmitted to the house. It passes through a stuffing-box, or any other device to keep the rain out, into a strongly-made box containing the following mechanism:—A wheel, b, is rigidly secured to this axle, so as to revolve with it. The periphery of this wheel is divided into, say, 32 teeth, corresponding to as many points of the compass. The number of these may be increased or decreased, the sensitiveness of the receiver being increased or decreased accordingly; the spaces between these teeth to be filled with ebonite, hard wood, or other insulating substance, and the rim turned smooth and true. e is a spring fixed to a brass pillar f, and armed at its tip with a piece of platinum, which rubs against the edge of wheel, and which must not be wider than one tooth of the wheel, though it may with advantage be somewhat less. The pillar f is connected, through n, with a battery x, the other pole of which is connected with the earth. Just below the wheel, and sliding on the same spindle, is a brass arm c (shown enlarged in Fig. 4). This arm fits sufficiently tightly to be carried round with the spindle when nothing opposes its motion, but not so tightly as to hamper the movements of the latter when it—the arm—is stopped by either of the brass pins d' d". For the sake of clearness, I have shown these pins further apart than they should be. In the actual thing they should be as close to the arm as they can be without simultaneously touching it. Now let us examine the action of this transmitter. Suppose the wheel b revolves in the direction of the hands of a watch; the arm c is carried round until it touches d', where it maintains contact, while b is at liberty to keep on revolving; as it does so the teeth on its edge rub, one after the other, against the platinum tip of e, and are thus, one after another, connected with the battery. As the ebonite pieces pass beneath the spring this connection is broken and the current ceases. Thus, for every tooth which passes beneath e a current or pulsation is sent into b, thence into c, and through d' to f', and along the line-wire attached thereto. If the wheel be turned in a contrary direction the same series of pulsations will be sent, but this time through d" and f" to the other line-wire. The mechanism of the receiver is represented by Fig. III. Enough is given to show the principle, but the details (the pawls p' p" for instance) require working out. On the outside of the box is fixed a dial (not shown), marked with 32 points of the compass. In the centre of this dial is a spindle, carrying a pointer, the movements of which correspond with those of the weathercock. On this spindle is a toothed wheel, r, having the same number of teeth as b (in this case 32). An electro-magnet on either side is so fixed that by attracting an armature attached to a spring a pawl, p, at the end of the latter pushes the wheel r one tooth round. It is clear that while m' will turn it in one direction, m" will move it in the other. A light spring, s, drops between the teeth so as to prevent accidental movements of the wheel. These electro-magnets are connected one to each of the line wires. It is obvious therefore that a current sent through either wire will turn the wheel, r, in one direction one tooth, two impulses will move it two teeth, and so on. Currents through the other line wire turn r in the reverse direction. One end of the wire on each magnet is connected to one of the line wires, the other end to earth.—Clatton.



E. L.

Travaux de l'Etat-major

L'Électricité

On lit dans l'*Akhbar*, d'Alger, numéro du 20 juillet :

Dans un projet de loi demandant ouverture de différents crédits supplémentaires sur l'exercice 1879, nous relevons, à propos du budget de la guerre, une demande de crédit de vingt mille francs pour le chapitre 3, « Dépôt de la guerre ». Les motifs de cette dépense sont assez curieux pour que nous les relations.

Voici les explications fournies par le gouvernement dans son exposé des motifs :

A la suite d'une entente avec le gouvernement espagnol, il a été décidé que les opérations relatives à la jonction trigonométrique de l'Algérie avec l'Espagne, par-dessus la Méditerranée, seraient exécutées en 1879.

Ce projet est le plus grandiose que la géodésie moderne ait été appelée à réaliser. Il s'agit, en effet, de mesurer des triangles dont la longueur des côtés dépasse trois cents kilomètres ; l'opération terminée, l'Algérie et la France seront reliées entre elles par une chaîne ininterrompue de triangles.

La méridienne de France s'étendra alors, sans solution de continuité, depuis les îles Shetland jusqu'aux confins du Sahara algérien, par une amplitude de trente degrés environ.

En raison de l'énorme distance qui sépare les sommets de la Sierra Nevada, en Espagne, des cimes de l'Atlas algérien, les appareils employés aux opérations ordinaires de la triangulation sont insuffisants pour assurer la visibilité réciproque des points du réseau hispano-algérien ; il est, par suite, nécessaire de recourir à des moyens d'illumination plus puissants que ceux que l'on obtient avec les appareils actuels. Après des recherches préalables, faites avec le concours des ingénieurs les plus éminents, il a été reconnu que l'électricité seule pouvait fournir une source de lumière assez puissante pour être perceptible à l'énorme distance de trois cents kilomètres.

Dans ces conditions, le Dépôt de la guerre est conduit à demander l'acquisition d'un matériel nouveau, qui comprendrait :

1° Six miroirs héliotropes de trente centimètres de côté ;

2° Six appareils réflecteurs de 0 mètre 50, pour les observations de nuit ;

3° Six lampes électriques à incandescence ;

4° Six machines Gramme, petit modèle, pour la production de la lumière électrique ;

5° Quatre moteurs ou locomobiles, de la force de deux chevaux-vapeur, pour actionner les machines électriques, chaque machine Gramme devant faire quinze cents tours par minute.

6° Un matériel secondaire, comprenant des courroies de transmission, des charbons, des lunettes de repère, des microscopes, etc.

Enfin, il y a lieu de prévoir la construction, fort dispendieuse en pays de montagnes, de baraques d'observation, de piliers et de collimateurs.

La dépense totale peut être évaluée à trente mille francs. Mais, dans le matériel dont il s'agit, se trouvent des machines Gramme et des moteurs qui resteront acquis au Dépôt de la guerre après la fin des travaux, et pourront alors être utilement employés dans les ateliers, pour lesquels on se proposait déjà d'en effectuer l'acquisition.

Il en résulte que la dépense relative aux opérations géodésiques peut être considérée comme diminuée d'une somme de dix mille francs, qui serait prélevée sur le budget normal du Dépôt de la guerre.

Le crédit supplémentaire demandé se réduit en conséquence à vingt mille francs.

On voit que la grande opération géodésique dont nous avons été les premiers à annoncer la prochaine exécution, va être tentée très-prochainement. Grâce au pouvoir lumineux de l'électricité, des mesures qui eussent été presque impossibles seront, très-sûrement, très-simplement terminées.

Pour se rendre compte des progrès accomplis grâce à l'électricité, il n'est pas inopportun de copier dans les Mémoires d'Arago les passages relatifs aux difficultés que l'illustre astronome a éprouvées à saisir les signaux qui lui étaient envoyés pour une opération analogue, la prolongation jusqu'aux Baléares de la méridienne de Paris :

« Nous partîmes de Paris, M. Biot et moi, et le commissaire espagnol Rodriguez au commencement de 1806.

« Nous visitâmes chemin faisant les stations indiquées par Méchain ; nous fîmes à la triangulation proposée quelques modifications importantes et nous nous mîmes à l'œuvre.

« Une direction inexacte donnée aux réverbères établis à Iviza, sur la montagne Campvey, rendit les observations faites sur le continent excessivement difficiles. La lumière du signal de Campvey se voyait très-difficilement, et je fus, *pendant six mois*, au Desierto de las Palmas, *sans l'apercevoir*, tandis que plus tard la lumière établie au Desierto, mais bien dirigée, se voyait tous les soirs de Campvey.

« On concevra facilement quel ennui devait éprouver un astronome actif et jeune, confiné sur un pic élevé, n'ayant pour promenade qu'un espace de vingt mètres carrés, et pour distraction que la conversation de deux chartreux dont le couvent était au pied de la montagne, et qui venaient en cachette enfreindre la règle de leur ordre. »

Nous avons pleine confiance dans le zèle et l'habileté des officiers d'état-major commandés par M. Perrier. Mais nous avouons ne pas comprendre pourquoi les lumières électriques à incandescence ont eu l'honneur d'être préférées à celles beaucoup plus puissantes que donnent les régulateurs Serrin, et nous serions fort aises d'être éclairés à ce sujet.

Nous ajouterons que, suivant nous, comme nous l'avons indiqué il y a déjà plus de deux ans, le meilleur emploi de l'électricité pour résoudre le grand problème de la figure de la Terre serait de se transporter dans les îles Pomotou et d'y mesurer un arc, à l'aide de triangulations à grande portée.

En effet, dans cet archipel lointain qui appartient désormais à la France dans son intégralité, les terres ne sont ni assez hautes, ni assez nombreuses pour défigurer la surface d'équilibre des eaux, et les anomalies locales au milieu desquelles se noient (même à sec, au milieu des continents) les météorologistes sont complétement éliminées.

SOMMAIRE

RÉGULATEURS ÉLECTRIQUES

DE LA PRESSION DU GAZ

Parmi les applications industrielles utiles de l'électricité, l'une des plus importantes est celle qui se rapporte à la régularisation de la pression du gaz d'éclairage dans les tuyaux de distribution. Cette question est étudiée depuis longtemps, et plusieurs systèmes plus ou moins complets ont été mis au jour; mais, jusqu'à présent, les applications que l'on en a faites ont été très-limitées. Cependant quelques-uns de ces systèmes fournissent des résultats satisfaisants, comme nous allons le voir.

Le gaz d'éclairage, comme on le sait, s'écoule à travers les tuyaux de distribution sous l'influence d'une pression exercée à l'usine par les gazomètres, et qui est réglée sur la moyenne de la consommation. Cette pression restant la même, il arrive nécessairement que la force avec laquelle le gaz s'échappe des tuyaux de distribution est d'autant plus grande que le nombre des orifices d'écoulement est moins grand. Or, comme ce nombre peut varier, soit qu'un certain nombre d'établissements qui consomment du gaz allument ou n'allument pas, soit qu'il se déclare dans un quartier des fuites ou que les compteurs fonctionnent mal, soit même qu'il y ait irrégularité dans le service de l'éclairage public dans les différents quartiers d'une ville, il peut en résulter, pour le consommateur et même pour la compagnie du gaz, de nombreux inconvénients dont le moindre est une dépense de gaz inutile (1). On comprend en effet que si, ayant réglé une première fois l'ouverture des becs, de manière à obtenir une bonne lumière, la pression vient à augmenter, le gaz qui s'échappe en trop grande abondance brûle imparfaitement, et, en se répandant dans les appartements, non-seulement les enfume, mais encore peut occasionner la détérioration des marchandises qui y sont déposées, altérer la santé de ceux qui les habitent et provoquer même des accidents les plus déplorables. D'après le témoignage des hommes compétents, il paraitrait que plusieurs incendies, entre autres ceux des Deux Magots, des magasins de Pygmalion, du Grand Opéra, de la rue Monge, de la filature de MM. Vilmot père et fils, et un grand nombre d'explosions de magasins, auraient eu pour origine la cause dont nous parlons, et on y rapporte même la mort du frère de l'école de Saint-Nicolas qui, d'après les constatations médicales, aurait été asphyxié par le gaz.

Ce qui est le plus fâcheux, c'est que souvent on ne se rend pas compte de cet accroissement de pression, car la lumière, au lieu de devenir plus brillante, s'assombrit, et l'on serait plutôt tenté d'ouvrir davantage le robinet d'alimentation des becs que de le fermer. On comprend qu'en présence de ces inconvénients, on pouvait désirer l'invention d'un révélateur et d'un régulateur automatique de la pression du gaz, et, comme je le disais, depuis une vingtaine d'années, plusieurs solutions ont été proposées par MM. Servier, Giroud, Launay, Raupp, Chardin et Prayer, etc.

Le système de MM. Giroud et Breguet, breveté en 1855, avait, non-seulement pour effet d'indiquer les variations de pression qui peuvent survenir dans les tuyaux de distribution du gaz, mais encore de régler automatiquement cette pression en ouvrant ou en fermant plus ou moins, à l'aide d'une

(1) Dans un article intéressant publié par M. Servier dans le journal *le Gaz* du 20 Mars 1859, on montre que sur 100 mètres cubes qui sont envoyés de l'usine, il n'y en a que 80 ou 90 d'utilisés, ce qui rend le prix de revient du gaz au lieu de consommation de 10 à 20 o/o plus élevé qu'aux gazomètres.

A SYSTEM OF ELECTRICAL STORAGE.

By Profs. Edwin J. Houston and Elihu Thomson.

The various suggestions which have hitherto been made for the storage of electrical energy, in such manner as to readily permit its after recovery in the form of electrical current, have failed when attempted to be carried into practice, either on account of their inherent impracticability, or by reason of the serious inconveniences and losses due chiefly to the following:

1st. The extent of conducting surface of the storage apparatus required to be acted on rendering it cumbrous.

2d. The loss of energy due to evolution of gas during the operation of charging.

3d. Lack of constancy and duration in the currents evolved after charging.

4th. The limited capacity for storage due to the proportion of active material being but a fraction of that present.

The well-known Planté secondary battery is open to all of the above inconveniences, and though admirable in its conception as a piece of scientific apparatus, yet lacks markedly the requisites of an economical reservoir for electrical action. In the secondary battery, as is well known, the duration of action is chiefly dependent upon the amount of surface of the lead plates employed; the action of the current used to charge it being practically limited to the surfaces of the plates, and the charge received may therefore be designated as due chiefly to polarization. Moreover, the charge received is necessarily limited on account of the evolution of gas.

Fig. 1.

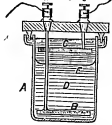

Fig. 2.

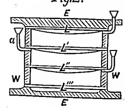


It is manifest that a Smee cell, or cell with vertical plates, in an acid solution, could not be used in the process, for the only effect would be the evolution of the gases hydrogen and oxygen from the decomposition of water.

In the system of electrical storage devised by us, the duration of action and consequent capacity for storage is independent of extent of surface and dependent on the mass of material to be acted upon.

In our method we employ a saturated solution of zinc sulphate, inclosed in a suitable vessel, at the bottom of which is placed a plate of copper, to which is connected an insulated conducting wire. At or near the top of the vessel, and immersed in the solution contained therein, is placed a second copper plate, or plate of hard carbon, or metal unchanged by contact with zinc sulphate solution, and less positive than metallic zinc. This is also connected to a wire. The storage cell so constituted is then ready for charging, which is effected by the passage through the cell of a current, whose direction is from the lower to the upper plate. The current employed is that obtained from a dynamo-electric machine, and the result produced is the deposition of metallic zinc on the upper plate, and the formation of a dense solution of copper sulphate overlying the under plate. The duration of the charging action is of course limited only by the amount of zinc sulphate and the thickness of the lower plate. The cell, after charging, constitutes in fact a gravity cell, and continues a source of electrical current until a reconversion of all the copper sulphate into zinc sulphate has been effected, metallic copper being deposited on the lower plate, and the deposit of metallic zinc being removed from the upper. It thus may be allowed to regain its original condition. The recharging, however, may be effected at any time, either before or after the cell has become inactive. The cell may be covered or sealed to prevent evaporation; and since no addition of new material is needed, a restoration to an active condition is at any time possible.

It is not necessary to employ zinc sulphate as the material to be decomposed, since other metallic salts may serve the same end, the only other requisite being that the lower plate shall yield to the solution a metal capable of redeposition, and the solution of which is denser than the solution employed in the cell, and that the upper plate be capable of receiving a metallic deposit and of retaining its form unchanged during prolonged use.

A, Fig. 1, represents a cell of glass, or other suitable material, furnished with two metallic plates, B and C connected separately by conducting wires to the binding posts, b and c, the wire from the lower plate being insulated. A porous diaphragm, E, is placed below the upper plate, C, to prevent fragments of deposited zinc from falling on the lower plate, which may occur should the charging current be too intense.

In charging, the arrangement of the cells in multiple-arc or in series may be adapted to suit the electromotive force of the dynamo-electric machine employed. The arrangement of the cells in charging may be different from that in discharging, according to the purpose for which the current is designed. Diffusive action of the solutions may be prevented by any of the well-known means used in gravity cells.

It may be objected that the economical results obtained in the storage of electricity as above described will necessarily be low, as but a fraction of the electrical energy in charging will be expended in overcoming counter electromotive force, or in effecting electrolysis, compared with that which overcomes the resistance of the liquid, and therefore lost in heat production. But this objection is readily met by so connecting the cells as to make their counter action or counter electromotive force the chief resistance to its passage. Economical results necessarily follow, the economy attained being measured by the relative cost of the fuel required to drive the dynamo-electric machine and that of the zinc and chemicals used for charging a battery of equal power to that of the storage battery used.

The resistance of the liquid between the plates of a storage cell may be lowered either by broadening the cell or by bringing the plates nearer together. In charging, economical results are obtained by using the plates comparatively near to each other, and separating them during discharge, and thereby avoiding loss by diffusion.

A convenient form of storage battery, designed for rapid charging and discharging, is shown in Fig. 2, where L, L', L'', L''' are horizontal plates of copper separated by insulating rings, W, W, the spaces between the plates, L, L', etc., being filled with a saturated solution of zinc sulphate. Lateral tubes, a, are provided to compensate for the expansion of the liquid due to changes of temperature, and also to provide for filling the cells. The cells are held between plates, E, E, by bolts which pass from one to the other. In this arrangement, the plates, L' and L'', serve as upper and lower plates, accumulating copper sulphate on their upper surfaces and receiving metallic zinc on their under surfaces. The series may of course be extended.

When a number of cells are connected in series, several of them may be charging, while the remainder are used as a source of active current.

The most obvious application of a storage battery furnishing a constant and lasting current, is to replace the ordinary telegraphic batteries; the objections to the direct use of the dynamo-electric machine being mainly the necessity for continually sustaining the driving power and preventing variations or intermissions therein; to adapt the current generated to the work to be done; and to sustain a uniform electro-motive force in said current. By the use of a storage battery, the dynamo-electric machine may be run at suitable intervals to produce and sustain the charge of said battery. The economy and convenience of this arrangement will, we believe, be vastly greater than with the ordinary batteries in use.

In lighthouses, a dynamo-electric machine can be run by suitable power at intervals during the day to furnish an unfailing and reliable source of current for lighting purposes.

The purposes for which the storage batteries may be applied are so numerous that mention need not be made of them, the feasibility of each being decided by the question of its economy.

In domestic economy it would be feasible to provide storage batteries to be charged by dynamo-electric machines from convenient central locations, the energy of said batteries to be used in the operation of burglar and fire alarm systems, or for light driving power.

It is practicable in good forms of dynamo-electric machines to realize in external work from 50 to 60 per cent. of the power used in driving them. Of this we believe it possible to store and recover 50 per cent., or even more. Therefore 25 per cent. of the original power may be given out secondarily as electrical current. If it be assumed that in the best steam engines it is possible that 20 per cent. of the heat energy of the coal be utilized, then about 5 per cent. of the heat energy might, we think, be recovered after storage as electrical current. Notwithstanding this small percentage, the economy would be much superior to the employment of zinc and other materials used in the ordinary battery in the production of current.—*Franklin Journal.*

Electricity as a Remedial Agent.

There are two methods by which electricity can be used as a remedial agent. One method is the temporary application of a strong current; the other is the constant application of gentle and scarcely perceptible currents. The strong currents referred to are furnished by the various electro-magnetic machines, manufactured for special medical purposes, or by regular voltaic batteries, as used in electric baths, while the gentle currents are obtained by the application to the body of peculiar arrangements based on the principle of the voltaic pile, and in which the natural perspiration of the skin, with its acid or alkaline reactions, takes the place of the acids or salt solutions used in the ordinary voltaic pile, and aided by the heat of the body, evolves a constant current which may be made to assist the vital energies, by its special action on the nerves, which are, as is well known, eminently good conductors of electricity, as they are of the nervous force. Notwithstanding the most recent researches have demonstrated that nervous force is not identical with electricity, they have proved the close relation of these two forces, by showing how electric currents act on the nervous system, and how muscular contraction induced by the nerves of volition can actually produce demonstrable electric currents, acting on the galvanometer in an identical way as in the case with the electric appliances, which are the principal subject of this article.

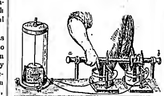
It was especially Dubois Raymond, who has made himself meritorious by investigating the capability of the muscles and nerves of volition to generate electric currents, and consequently the inverse operation. He saved animal electricity from the disrepute into which it had been brought by Mesmer, who as is now well known, acted only upon the highly wrought imagination and sensibilities of his patients, while his appliances were so absurd as not to stand the critical test of even a merely superficial scientific examination.

We consider the experiments of Dubois Raymond so important in connection with the subject of this article, that we give a short description of one of his experiments, proving that the generation of electricity by the nerves of volition, does not only belong to electric fishes, or to the animalcula which produce the luminosity of seawater, in our summer nights, but also to man himself; from which follows necessarily that similar electric currents as can be produced by the nerves and muscles, will react on them and all the tissues of the body, and when properly applied may exert a most beneficial influence.

The method by which Du Bois Raymond proves that electric currents are generated by the contraction of the muscles, induced by the nerves of volition, consists in connecting with the ends of the coils of a sufficiently sensitive galvanometer, the two metallic handles of an ordinary small medical electric machine; they are grasped with the moistened hands, the needle will then come in motion by irregular currents developed, but after some oscillations come to rest. If now the muscles of one arm and hand are contracted, the needle will deviate to one side, for some 10 or 20 degrees; if then these muscles are relaxed and those of the other hand and arm contracted, the needle will at once deviate to the other side, and may be made to deviate more, and so by alternate contraction and relaxations of the muscles of both arms at the right time, deviations of the needle of 40 to 50 degrees may be produced, provided the galvanometer coil contains from 0000 to 4000 windings of fine wire.

The adjoined figure represents a modification of the experiment which Du Bois Raymond made later:

In two separate glass vessels containing salt water, two strips of platinum are plunged connected with the terminal wires of a very sensitive galvanometer with astatic needles, suspended in a coil of 24,000 convolutions. A wooden rod *ab* is over the vessels and so near to it, that while grasping it, a finger of each hand can be immersed in the liquid. When now the bar is squeezed with one hand, and the muscles of the corresponding arm are contracted, taking care not to move the fingers immersed in the liquid, the needle will deviate, and this in such a direction as to indicate that the current runs from the arm which is not contracted, through the salt water in one vessel, the galvanometer coil and the salt water in the other vessel, to the arm of which the muscles are being contracted. It is evident therefore that as the current moves in a closed circuit, it will run in the body from the contracted to the non-contracted member, and that contraction evolves positive electricity, which discharges in the body to non-contracted parts,



ELECTRICITY DEVELOPED BY MUSCULAR CONTRACTION.

which can therefore give out positive electricity, which will be absorbed from the outside by the contracting parts, if they are in contact with conducting substances.

It is curious that experiments have proved that if frogs' legs are thus connected, and caused to contract, the current runs in the opposite direction, it shows a difference in the relative arrangement of muscles and nerves in frog and in man. Or it may be that there is a difference in the current when muscles are contracted by volition as is the case when men thus experiments, while with the frog, they can only be caused to contract by the reflex action, produced by stimulating the parts we wish the animal to contract.

It has been suggested that these currents are developed by the heat evolved in contraction, by sanguine congestion or by the increased perspiration of the contracting member, but Raymond proved directly by studying the subject practically, that if these causes produce currents they run in opposite directions, as the currents evolved by voluntary contraction.

These gentle electric currents continually circulating in the human body are confined to the interior by the epidermis (upper skin) which is a bad conductor of electricity, and their presence can only be demonstrated by special arrangements. Du Bois Raymond proved this also, when he blistered the surface of the parts in contact with the salt water or better with the platinum plates attached to the galvanometer; while with the epidermis he obtained a deviation only 2° to 8°, he obtained as much as 00° or when the contact was made after removal of epidermis by blisters.

It is to be hoped that the field opened by him will be taken up by other equally able hands and our knowledge of one of the most influential secret and subtile agencies of living organisms as far extended as possible, and as the subject so fully deserves. Surely the fact that muscular contractions produce electric currents, as that electric currents cause muscular contractions, is a most important and suggestive which some day will lead to important discoveries.

Mining & Scientific Press
May 21, 1881.

An Electric Soldering Iron.—Mr. Ball, of Philadelphia, has patented a soldering-iron capable of melting the hardest solders, as those of gold and silver, by electricity. The electrodes pass through and project beyond the handle, and are connected with a ball of platinum; this, when battery connection is complete, becomes heated to any required degree, and the desired soldering is readily affected.

Telegraphic Journal

THE ELECTRIC DISTANCE MEASURER OF M. G. LE GOARANT DE TROMELIN.

April 1880

The question of the rapid measurement of the distance separating a moving object from a point of observation, has often been considered by various inventors. The problem resolves itself into this: There being two given points of observation, O O', separated by a distance of say 1,200 metres, to find immediately, and without calculation, the distance of a movable point, N (see fig. 1), from the observatory, O. If O O' represents the base of 1,200 metres, and O A the distance separating the limit, L, of the centre of rotation of the pointer, A a, it is evident that if A a is parallel to O' N, the triangles, O n A and O N O', being similar, n O will represent on the table, T T, the distance of O from N on the same scale that O A bears to O O'.

This being granted, suppose that from the two observatories, O O', the telescopes, L and L', are turned towards the point, N; then if by electrical means we cause the pointer, A a, to move always parallel to the telescope, L', the two similar triangles, of which we spoke, will always be automatically formed, and the point of intersection of the pointer, A a, with the graduations, R, engraved on the telescope, L, and which are graduated to the scale of $\frac{O A}{O O'}$ will give at once, by a direct reading, the distance, O N, which is required.

In order to obtain parallelism between the telescope, L', and the pointer, A a, let us suppose a toothed sector, S, to be fixed to L', and made movable by means of a tangent screw, V, turned by a handle, M.

The telescope, L, and the pointer, A a, are set parallel once for all when the instrument is adjusted. A wheel, P, fixed to the axis, b b, of the tangent screw, and provided with an interrupter, I, can produce a number of interrupted currents, so that the escapement of a receiver, regulated by the wheel P, causes the pointer, A a, to follow the angular movements of the telescope, L'.

This principle has been effected by various persons; the object aimed at has been the same, but the means by which they have been arrived at are very different.

M. Siemens, well-known by his electrical inventions, has employed the armature which bears his name to effect this result.

On the axis, b b, he placed a multiplier wheel, connected with his armature, which turned between the poles of a powerful magnet.

By making the sector, S, turn, he produced at the same time a rotation, more or less rapid, of the armature, which produced reversed induced currents at each half revolution. These currents, transmitted to the receiver, O, constituted a motive force which caused the movement of the needle, A a, by means of a system of propelments, driven by an armature oscillating between the branches of an electro-magnet, polarised by a magnet in V.

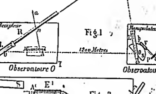
This system was, as is evident, the application of the *transmission* of force to a distance by the magneto-electric machine which M. Siemens had invented.

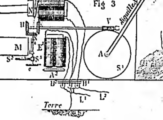
Although ingenious, this system possessed a great defect; in fact, it was impossible to produce a sufficient current without exerting considerable manual exertion, and this was aggravated by the multiplying power of the wheel work. If the manipulator was turned slowly, the currents induced had not sufficient power to move the pointer, which was nearly a metre in length. If the apparatus was turned too quickly, the number of currents transmitted was so considerable that the propelments did not respond at all in consequence of the inertia of the long pointer, A a. In any case the motive force was so slight that the wind alone was sufficient to prevent the pointer moving, and consequently parallelism from being preserved.

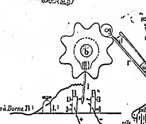
This system was tried for some time at Brest, and had to be given up.

We have spoken at some length about this *telemeter*, because it is one of the first applications of the transmission of force to a distance, and because it was in France that it was first applied; in fact, because it had features distinct from similar forms of apparatus.

The inconveniences which we have pointed out do not exist in the telemeter of M. de Tromelin. The electricity being only used for regulating an escapement driven by clockwork, it is evident that the motive force can be sufficiently considerable to effect the object aimed at. The problem to be solved is that of the movement of the pointer, A a, in the two directions. It is necessary that the observer, having followed a particular point with







Détails du distributeur du courant au manipulateur

Fig. 2.

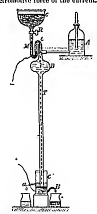
the pointer in one direction, shall be able to follow any other point by using the pointer in the reverse direction.

Description.—The manipulator is made as shown by fig. 1; fig. 2 shows details of the same. As can be seen, the wheel, P, has 8 cams, which, by raising the jockey wheel, g, during the rotation of the former, produces at d interruptions of the current given out by the battery, P, and which flows to line, n. The spring, r, is sufficiently strong to cause the jockey wheel, g, to lie in the hollow of the cam wheel when the handle which turns the wheel round is left to itself. A reversor, I, mounted friction tight on the axis, b, allows either the positive

way as to show to the astronomers of Mars...

DEBRUN'S ELECTRO-CAPILLARY GENERATOR.

The most sensitive of all electrometers hitherto invented is that known as Lippmann's capillary electrometer. It is based on the principle discovered by Herr Lippmann, that if by mechanical means we deform a mercury surface, that deformation produces a disengagement of electricity which tends to arrest the movement of the mercury. The electrometer is based on the converse of this principle and the electricity to be measured is caused to produce a mechanical movement in a mercury surface confined in a capillary tube, and this movement is measured by means of a very fine scale. In the actual electrometer, as now manufactured and sold in Germany, the mercury appears as a column in the capillary tube, and the upper surface of the column is in contact with a superposed column of dilute sulphuric acid. When, therefore, one pole of the battery to be measured is connected to the mercury and the other to the acid, there is a movement of the upper surface of the mercury within the tube, either up or down according to the "sign" of the poles, and to a degree corresponding to the electromotive force of the current.



It follows, of course, that if such a movement could be communicated to the mercury surface mechanically an equivalent electromotive force would be produced, and hence it would be possible to construct a generator of electricity on this principle. M. Debrun, preparer to the Faculty of Sciences, Bourdeaux, has in fact devised such a capillary battery, and his arrangement is represented in the figure. In a tapering capillary tube T he causes mercury to fall drop by drop in such a manner as to form a string of capillary beads or globules having acidulated water (dilute sulphuric acid) interposed between each pair of globules. The mass of mercury M which forms the first globule is in communication with a platinum wire electrode, as shown, and therefore takes its polarity, which, following the figure is negative. Similarly the mass of mercury C' forming the final globule is connected to another platinum wire which is marked positive in the figure. The fountain-head of mercury is contained in a reservoir C, and its flow into the capillary tube is regulated by the stop-cock R. The water, acidulated by one-sixteenth, is drawn out of the globular reservoir B by the passage of the mercury drops, and a Mariotte flask A is employed to maintain its level constant. At the lower end a Florence receiver permits the acidulated water to escape by the nozzle a and the mercury by the nozzle B into separate receptacles. The extremity of the tube should be immersed in the mercury C', or else the dilatation of the globules at the extremity will tend to generate a current in a contrary direction to that developed by the descending globules.

The tube used by M. Debrun has at its upper end a diameter of 2½ millimetres dwindling to 1 millimetre at its lower end. It should be arranged to give a height of 0.30 metres and to contain at least twenty globules of mercury and not more than thirty-five. In these conditions the electromotive force obtained as measured by the mercury electrometer of Herr Lippmann, is about 1.4 volts, which is sufficient to decompose water by means of Wollaston points. The energy absorbed by the apparatus in generating the current is represented by 2 kilogrammes of mercury falling a quarter of a metre per hour. Nevertheless M. Debrun has been able, in making the generator operate during twenty-four hours, to strongly silverise a five centime piece and from this data he has been able to compute that while the work absorbed was 0.5 kilogram-metres per hour, the work done amounted to 0.4 kilogram-metres.

If the two poles of the apparatus are separated, the mercury flows gently and with difficulty, if on the other hand they are united, the mercury flows rapidly; and its motion can even be arrested by opposing a Bunsen element to the capillary battery.

The electrician will readily understand that in order to test the current a galvanometer of high resistance is necessary owing to the great resistance of the capillary column.

MINERAL WEALTH OF EUROPEAN ...

LE NOUVEAU FREIN ÉLECTRIQUE

DE M. ACHARD

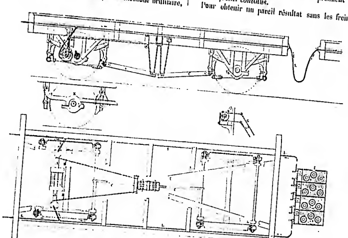
La Nature 1880

Avec les vitesses éliminantes des trains des chemins de fer actuels, vitesses qui dépassent quelquefois 100 kilomètres à l'heure, — 28 mètres par seconde — il est indispensable de disposer de moyens d'arrêts puissants, rapides et sûrs.

L'arrêt instantané, tel que le rêvent encore certains inventeurs ignorants, étant une chimère, comme le mouvement perpétuel, on se contente d'agir, faute de mieux, par la méthode ordinaire, qui consiste à venir appliquer des sabots sur les roues des voitures pour enrayer leur mouvement. Si le principe est resté le même, les méthodes d'application ont du moins beaucoup varié, et c'est une solution très élégante et aujourd'hui très perfectionnée de la question des freins continus que nous voulons faire connaître aux lecteurs de *la Nature*.

On obtient un arrêt rapide *en agissant sur toutes les roues d'un train à la fois*; les appareils qui permettent de réaliser cette condition prennent le nom de *freins continus*.

Pour obtenir un pareil résultat sans les freins



Frein électrique de M. Achard. — Disposition nouvelle du chemin de fer de l'Est (1879). — I, batteries secondaires avec piles Daniell pour les charger; L, L, conducteurs; A A, électro-aimant tubulaire; D D, essieu qui entraîne l'électro-aimant, en fonction lorsque le courant passe; C, C, leviers moulés soulevés par les chaînes au moment du serrage; D, D, sabots de serrage en fonte; H, commutateur disposé sur le fourgon de tête; G, G', cordes allant du fourgon de tête à la locomotive. En tirant G', le mécanicien produit le serrage, et le desserrage en tirant G. On manœuvre le frein sur le fourgon d'arrière en agissant sur une manette analogue à celle du commutateur H.

continus, on serait obligé d'employer un garde-frein par voiture, condition irréalisable dans la pratique.

A côté de la question de continuité d'action se place l'instantanéité d'action; on devine sans peine l'importance de ce facteur, chaque seconde perdue rapprochant l'obstacle de tout le chemin parcouru par le train, dans le même temps. L'action instantanée de l'électricité donne au frein Achard cette propriété qui ne se retrouve qu'à un moindre degré dans tous les autres systèmes, — vide ou air comprimé — aussi peut-on, avec le frein électrique, obtenir des arrêts aussi rapides et aussi puissants qu'avec aucun autre.

Reste la question de sécurité d'action. Il est très important, à ce point de vue, de disposer d'un appareil toujours en état de bon fonctionnement, ou nous avertissant lui-même de ses dérangements, s'il en arrivait. L'insuccès des freins exceptionnels, dits *freins de détresse*, destinés à produire des arrêts rapides en cas de danger imminent, tient à ce qu'ils n'étaient jamais en état de fonctionner au moment même où on réclamait leurs services; les freins doivent donc être utilisés en service courant; et, d'autre part, avertir s'il leur arrive un accident de nature à compromettre leur bon fonctionnement.

Les appareils qui satisfont à cette dernière condition sont dits *automatiques*.

STATISTIQUE. — *Prix Montyon* accordé à M. V. de Saint-Genis. La Commission accorde en outre : à M. Borius, le rappel du prix qu'il a obtenu en 1875 ; un encouragement de la valeur de 400 francs à M. G. Le Bon et une mention très honorable à M. Hannauge.

CHIMIE. — Le *prix Jecker* est partagé de la manière suivante : M. Riban obtient 1000 francs, M. Bourgoin 1000 francs et M. Crafts 2000 francs. — *Prix Lacaze*, décerné à M. Lecoq de Boisbaudran.

GÉOLOGIE. — Le *grand prix des sciences physiques*, dont le sujet était l'étude approfondie des ossements fossiles de l'un des dépôts tertiaires situés en France, est décerné à M. Filhol. Une récompense de 1000 francs est accordée à M. Lemoine.

BOTANIQUE. — Le *prix Barbier* n'est pas accordé, mai un encouragement de 1000 francs est attribué à M. le docteur Manouvriez. — Sur le *prix Desmazières*, deux encouragements de 750 francs chacun sont accordés, l'un à M. Crié, l'autre à M. le docteur Leudiger-Fortmorel.

ANATOMIE ET ZOOLOGIE. — Le *prix Thore* est décerné à M. Eduart Brandt.

MÉDECINE ET CHIRURGIE. — *Prix Montyon*. — La Commission décerne trois prix : à MM. Dujardin-Beaumetz et Audigé, à M. Villaux et à M. Auguste Voisin. Elle accorde trois mentions honorables : à M. Bochefontaine, à M. Lérorché, à M. Simonin, et cite honorablement dans le rapport : MM. Azam, G. Delaunay, Grasset, Gréhant, Poncet, Parak, Riembault. — *Prix Bréant*. Un prix de 5000 francs est décerné à M. Toussaint. — *Prix Godard*. La Commission décerne deux prix, de 1000 francs chacun, à MM. Alph. Guérin et Ledouble. — *Prix Chaussier*. Le prix est décerné à feu M. Ambroise Tardieu.

PHYSIOLOGIE. — *Prix Montyon : physiologie expérimentale*. — Le prix est décerné à M. François Franck. — Le *prix Lacaze* est décerné à M. le docteur Ravaine.

PRIX GÉNÉRAUX. *Prix Montyon : arts insalubres*. — Le prix est décerné à MM. Boutmy et Faucher. Un encouragement de 1500 francs est accordé à M. le docteur Ilam. — *Prix Cuvier*, décerné à M. Studer. — *Prix Trémont*, à M. Tholion. — *Prix Gegner*, à M. Baugain. — *Prix Laplace*, à M. C. M. Walckenaer, sorti le premier en 1879 de l'École Polytechnique.

Un prix de 5000 francs est accordé à M. William Crookes, pour l'ensemble de ses expériences.

STANISLAS MEUNIER.

La Nature. March 6 188

TÉLÉMÈTRE ÉLECTRIQUE

DE M. G. LE GOARANT DE TROMELIN

Lieutenant de vaisseau

Le nouveau télémètre que nous allons décrire, en reproduisant les dessins de *La Lumière électrique* est une solution très élégante du problème suivant :

Déterminer, par une simple lecture, exactement, rapidement et à chaque instant, la distance d'un objet mobile, éloigné et inaccessible.

Le principe de l'appareil est représenté fig. 1.

On vise de deux observatoires O,O' placés à une distance connue, 1200 mètres, par exemple, le point N, dont on veut connaître la distance à l'observatoire O. Si, par un procédé quelconque, nous obligeons une droite *An*, tournant autour du point A, à rester *toujours parallèle* à l'axe de la lunette O'L' de l'observatoire O', nous formerons deux triangles semblables OAn et OO'N. Si la distance OA est de 1^m,20, le côté OO' ayant 1200 mètres, il en résultera que chaque *millimètre* sur le côté On correspondra à une longueur de *un mètre* sur le côté ON et que, en lisant la distance *On* exprimée en millimètres sur une règle graduée R, ce nombre sera l'expression *en mètres* de la distance ON. Maintenir toujours le parallélisme entre la droite *An*, et l'axe de la lunette O'L', tel est le rôle de l'électricité dans le télémètre de M. de Tromelin.

L'appareil se compose donc de deux parties distinctes, un *manipulateur* placé en O' ; il a pour effet de distribuer des courants électriques qui dépendent du mouvement de la lunette L', et d'un *récepteur*, qui utilise ces courants pour faire mouvoir l'aiguille *An*. L'ensemble constitue une sorte de télégraphe à deux fils.

Manipulateur. Il se compose d'une lunette L' (fig. 1), portant un secteur denté S mis en mouvement par une vis tangente V, reliée à une manivelle M. En tournant cette manivelle dans un sens ou dans l'autre, on fait tourner la lunette à droite ou à gauche, ce qui permet de suivre l'objet mobile.

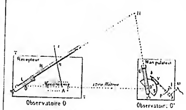


Fig. 1. Mode d'emploi du télémètre électrique.

Sur l'axe de la vis tangente est placé le *distributeur de courants*, représenté figure 2, et dont nous allons étudier la fonction.

Une roue à 8 cames est fixée sur l'axe de la vis Un galet *g*, relié à une tige *r* formant ressort, s'appuie constamment sur cette roue.

Lorsque le galet est dans un creux, le ressort *r* ne touche pas la pointe *d* et le courant venant de la pile F ne passe pas dans le fil relié à la borne B' du récepteur. Si on tourne la manivelle de droite à gauche, le plateau tournera ; il y aura un contact en *d*, et par suite une émission de courant, chaque fois qu'une des cames du plateau sera en face du galet *g*.

Pour chaque tour de la vis sans fin il y aura *huit* émissions de courant, le récepteur recevra huit fois le courant électrique, l'aiguille *An* se mouvera sous l'influence de ces courants, comme nous verrons tout à l'heure.

Relativement à l'opinion de la commission sur la nécessité de s'affranchir à tout prix des crues du Chagres, les auteurs du projet ont pensé que l'on pouvait résoudre la difficulté, en réglant l'écoulement des eaux de cette rivière dans le canal, à l'aide d'un barrage à déversoir régulateur, d'une longueur de 1.500 mètres, et d'une hauteur maximum de 38 mètres ; ou encore de construire un lit mineur pour le Chagres. Ces solutions, qui peuvent être modifiées par des études plus approfondies, entraîneraient de grandes dépenses, et porteraient les frais de construction, d'après la commission, à 1 milliard 70 millions et la durée des travaux à douze années. En tout cas, la commission préférerait voir adopter la dérivation complète du Chagres, en lui creusant un chenal artificiel, pour mener ses eaux à la mer.

Au cours des travaux de la commission, un nouveau projet, variante des deux précédents, a été proposé.

Les dispositions de ce projet sont les suivantes :

Les deux chaînes entre lesquelles se trouve comprise la vallée du Chagres formant, en certains points, d'étroits défilés, on en profite pour barrer la vallée en un de ses points, et relever le niveau des eaux du fleuve ; on crée ainsi un lac artificiel, une sorte de lac Nicaragua, à la cote de 24 mètres, auquel on donne, en des endroits convenables, un écoulement dans les vallées latérales, pour le trop-plein des eaux du fleuve, qui s'écoule vers la mer par cinq écluses accolées au barrage. Du côté du Pacifique, la même disposition serait adoptée pour le Rio-Grande.

Ce nouveau projet, dans la pensée de ses auteurs, permet d'éviter les travaux à faire pour creuser au Chagres un nouveau lit ; de diminuer les terrassements, et, par suite, de réduire en proportion le chiffre des dépenses.

Avec cette modification, le Canal deviendrait un canal à écluses et il en nécessiterait 13.

Une remarque qui s'applique aux trois projets par l'isthme de Panama, c'est que les mouvements volcaniques sont arrêtés depuis longtemps dans cette région de l'isthme américain, ce qui, au point de vue des tremblements de terre, est un gage de grande sécurité pour l'avenir.

TRACÉ PAR L'ISTHME DE SAN-BLAS. — La nature du terrain ne comporte dans ce projet qu'un canal à niveau. Il a son origine dans la baie de San-Blas, non loin de l'embouchure du Necarlegua, et aboutit, comme le précédent, dans la baie de Panama.

La commission n'a eu pour l'examen du projet que des renseignements insuffisants ; cependant elle a apprécié que les travaux à exécuter pour emprunter une portion du Bayano seraient très-coûteux et très-aléatoires ; le tracé comporte, en outre, un souterrain de 10 kilomètres de longueur, qui ne permettrait pas de livrer le Canal avant une douzaine d'années. La dépense de construction a été évaluée à environ 1 milliard 270 millions. De pareilles conditions n'ont pas semblé de nature à recommander le projet, qui n'a pas été pris en considération.

TRACÉ PAR L'ATRATO-NAPIPI. — Le canal partirait de l'embouchure de l'Atrato, dans la baie d'Uraba, emprunterait le cours de cette rivière, presque au confluent du Napipi, et aboutirait non loin de la baie de Cupica. Deux projets ont été présentés, l'un d'un canal à écluses, l'autre d'un canal à niveau, comportant chacun un tunnel. Pour les deux, la longueur serait de 290 kilomètres environ et la durée du passage de trois jours.

Nous ne nous occuperons que du canal à niveau, le projet de canal à écluses ayant été abandonné par son auteur avant que le Congrès se fût prononcé définitivement.

Le projet à niveau a paru présenter plusieurs difficultés techniques des plus sérieuses. L'une de ces difficultés réside dans les travaux considérables qu'il y aurait à faire à l'embouchure de l'Atrato, pour obtenir sur la barre et y entretenir plus tard une profondeur constante de 8 mètres 50. Au prix de sacrifices énormes on n'a pu arriver à 7 mètres 50, à l'embouchure du Mississipi, dans la passe sud ; mais on était aidé par les grands courants de la mer : ce qui ne se présenterait pas pour l'Atrato, placé au fond d'un golfe profond. Il faudrait, de plus, recevoir dans le canal la totalité des eaux de la Vallée du Napipi, et la commission a vu dans cette nécessité la production probable de courants très-nuisibles à la navigation.

Outre les difficultés techniques qui viennent d'être signalées, il y a lieu de tenir compte encore de ce fait, que la contrée est la plus humide de tout l'isthme américain, qu'elle est dépourvue de matériaux de construction, à l'exception du bois, qu'elle n'a qu'une très-faible population, et qu'enfin elle est alternativement si montueuse et si marécageuse qu'il faudrait un travail énorme pour y établir les chemins de service indispensables.

En conséquence, la commission a estimé que le projet par l'Atrato-Napipi ne présentait pas de bonnes conditions techniques.

La durée d'exécution serait probablement de 10 à 12 ans, et la dépense de construction d'environ 1 milliard.

Il restait à la commission à se prononcer sur les cinq grands tracés qui lui avaient été soumis, et sur les projets divers présentés pour chaque tracé.

En présence des avantages et des inconvénients de chacun, la commission a émis l'avis que le canal à construire devait être dirigé à travers l'isthme de Panama par la baie de Limon et Panama, en se réservant de faire son choix entre le canal à niveau et le canal à écluses. Une seule chose pouvait faire pencher la balance en faveur du canal à écluses, c'était l'évaluation des dépenses d'établissement qui n'ont été portées par la commission qu'à la somme de 570 millions environ, tandis que le canal à niveau ne pourra être construit à moins de 1 milliard 70 millions environ, à moins de circonstances exceptionnellement favorables.

La commission a pensé que l'on ne devait pas s'arrêter devant cette grande différence des chiffres d'estimation des dépenses, que, même avec le chiffre de 1 milliard 70 millions, le canal à niveau sera rémunérateur, en prenant pour base le passage de 4 millions de tonnes (chiffre inférieur aux évaluations statistiques), au prix de 15 francs par tonne, et finalement elle a recommandé le canal maritime à niveau devant être dirigé du golfe de Limon à la baie de Panama.

Conformément aux conclusions concordantes des rapports de ses différentes commissions, le Congrès International, dans sa séance générale de clôture du 29 mai 1879, a pris la décision suivante :

Le Congrès estime que le percement d'un canal interocéanique à niveau constant, si désirable dans l'intérêt du commerce et de la navigation, est possible ; et que ce canal maritime, pour répondre aux facilités indispensables d'accès et d'utilisation que doit offrir, avant tout, un passage de ce genre, devra être dirigé du golfe de Limon à la baie de Panama.

(*La fin au prochain numéro.*)

B. LUNEL.

ERRATUM. — Une faute d'impression s'est glissée dans la légende de la carte de l'isthme, que nous avons publiée dans notre dernier numéro. Ce n'est pas à 170 millions, mais bien à 1 milliard 70 millions que s'élèveraient les dépenses du canal à niveau constant par le Limon et Panama, ainsi que nous l'indiquons dans l'article ci-dessus.

ELECTRIC INDICATOR FOR STEAM BOILERS.—It is said an electric boiler indicator has been brought out in France, by means of which the water level in a boiler may be ascertained at any distance from the boiler. A tablet is connected with the electric indicator, which is fixed at the top of a vertical tube above the boiler, by two electric conducting wires. An index, a battery and a bell complete the apparatus.

Engineer

ELECTRICITY.

July 21 1880

The Commonwealth Electric Lighting and Manufacturing Company of Philadelphia is a corporation which came into legal existence on the 22d, by the granting of a charter by the State Department at Harrisburg. The objects of the company, as set forth in its application, are to manufacture and supply electricity for illuminating purposes, and also lamps, burners and other necessary appliances for the same.

The life of a submarine telegraph cable is from ten to twelve years. If a cable breaks in deep water after it is ten years of age it cannot be lifted for repairs, as it will break of its own weight, and cable companies are compelled to put aside a large reserve fund in order that they may be prepared to replace their cables every ten years. The action of the sea-water eats the iron wire completely away, and it crumbles into dust, while the core of the cable may be perfect. The breakages of cables are very costly, and it is a very difficult matter to repair them in comparison with land lines. A ship has to be chartered at an expense of $500 a day for two or three weeks in fixing the locality and in avoiding bad weather, as cables can only be repaired in the calmest seasons. One break alone in the Direct Company's cable cost $100,000 to repair, and the last chance left to the company was to make an agreement with the Anglo-American, so that they should be protected and have the use of that company's line when their own was stopped.

Electricity in the Human Body.

Druggist Circular Jany 1880

Most people are familiar with the "sparks" which may be produced under certain conditions by stroking the fur of a cat; and travellers in Canada and other cold, dry countries have witnessed the still more remarkable phenomenon of the human body being turned into a conductor of electricity, and the possibility of lighting the gas by merely placing one's finger—given the necessary conditions of electrical excitement—near the gas jet, without any other agency. Mr. A. W. Mitchinson, the African traveller, who is engaged in writing a narrative of his exploring expeditions in West Central Africa, gives some still more startling facts. He states that one evening, when striking an African native, in a moment of anger, with a cowhide whip, he was astonished to see sparks produced, and still more surprised to find the natives themselves were quite accustomed to the phenomenon. He subsequently found that a very light touch, repeated several times, under certain conditions of bodily excitement, and in certain states of the atmosphere, would produce a succession of sparks from the bodies of native men as well as native cattle. A lazy nigger, it seems, yielded none of these signs of electricity—a rather unfortunate circumstance for his more active brethren, who may possibly come in for a share of undeserved flogging from the hands of future travellers in search of electrical phenomena among the human race. We are not aware that these facts have been recorded by other travellers, but they certainly deserve thorough sifting by competent observers.

ELECTRIC SPARKS.

Electricity for Lighting and Extinguishing Lamps. — A French journal describes two new and ingenious pieces of electrical apparatus for lighting and extinguishing lamps. In one of them (M. Margret's system) the oil-lamp stands on a base in which is a horizontal electro-magnet. From the armature of this rise two parallel curved rods of copper, joined at the top by a platinum spiral, which is rendered incandescent by a battery current, and brought in that state to the wick, when the armature is attracted. In this movement towards the wick, a small bellows is compressed, giving a puff of air through a tube rebounding on the wick. In the case of lighting the lamp, this puff has no effect, but when the lamp has been burning, and is to be extinguished, the puff produced by a momentary passage of the current blows the flame out, and there is not time for the spiral to relight the lamp. In the other system (that of M. Ranque), a platinum spiral is brought to the wick, much in the same way, but the lamp is put out by an extinguisher at the end of a curved and pivoted wire. The contrivance is such that the extinguisher is brought down to the wick, or raised from it (through attraction of the armature), according as the flame is to be put out or lighted.

An Electrical Elevator. — Dr. Siemens, who appears to be indefatigable in seeking to extend the sphere of usefulness of electricity, has brought out an electric elevator, which he has been exhibiting at Mannheim, Germany. Its construction appears to be simple, and suggests an easy method of putting in safety brakes. The cage is carried by wire ropes, having counter-weights, so that the cage, when loaded, is practically in equilibrium. The current generator at the base is electrically connected to the dynamo-machine in the cage, and the latter actuates two toothed wheels, taking into a metal rack running up the centre of the passage-way of the lift.

Electricity in Surgery. — Trouvé's utilization of electricity in combination with surgical instruments is bearing fruit. A case is recorded from Vienna in which a doctor has succeeded in curing a cancer in the stomach, mainly by the assistance rendered by the polyscope. The electric probe, which rings a bell when a ball or any metallic substance imbedded in the muscles is reached, is highly prized by army surgeons, and an application of the same principle to surgical forceps has enabled a Berlin oculist to save the eye of a workman, which was damaged by the intrusion of a spark of steel. This case had become so urgent that it was necessary to extract the piece of metal without delay, or to excise the eye; but Dr. Hirschberg, by inserting a soft iron probe, and subsequently converting it into an electro-magnet, withdrew the particle of metal, and saved the eye.

CORRESPONDENCE.

Electrician

GALVANOMETERS.

Ar July 24 1880

TO THE EDITOR OF THE ELECTRICIAN.

Sir: While reading the article on the Deprez galvanometer in *The Electrician* of June 5th, received a few days ago, my attention was engaged by the following paragraph, which I quote for the purpose of making a few comments, which I hope will not encroach too heavily on your space:—"If the current from a powerful battery be passed through the coils of a large electro-magnet, and studied by means of this galvanometer, the intensity of the current may be seen to vary and to increase during a considerable period of time, which under special conditions may extend to a minute, that is to say, the production of the magnetic effect is not completed until the end of this period, during the whole of which the inductive reaction of the electro-magnet is appreciable and continuously decreasing. This remarkable phenomenon, discovered, so to speak, *en passant*, by M. Marcel Deprez, shows what services may be rendered by the instrument we have described."

We see from this quotation that the Deprez galvanometer shows an inductive effect of the magnet on the coils during the first period of time the current is passing through the coils. It must be, therefore, that during magnetisation there is a motion of the lines of force in such a direction as to tend to the production of an opposing electromotive force when the coils cut them as they pass by. On the other hand, the second series of researches of Lord Elphinstone and C. W. Vincent, F.R.S.E., demonstrates plainly that the electromotive force produced in the helices by demagnetisation of electro-magnets is in the same direction as the original current; whence, it appears that in this case the motion of lines of force must be contrary in direction to that in M. Deprez's experiment.

Now, these two experiments just noted may seem to have no apparent connection with each other; but I will endeavour to show that they become interestingly related as a foundation of actual proof to one of Faraday's most beautiful conceptions of lines of magnetic force. Faraday, it is known, imagined lines of force to spring out around conductors and expand concentrically around them as centres, just as the ripples produced by a pebble falling in the water; and that they increased outwards, as new lines originated at the centre, until this outside tension balanced the producing current in the conductor; that when the current was interrupted these lines shortened upon themselves or contracted back towards the centre. But this explanation of Faraday has not gone far beyond the hypothetical state in the opinion of many scientists, especially those whose confidence still lingers in Ampère's doctrines, because a palpable demonstration of the theory has been lacking. With isolated linear conductors, or with helices, the experimental observation of this motion of lines of force has always been totally unsatisfactory, on account of its extremely short duration under those circumstances; but when we call to our assistance a paramagnetic body like iron, as in electro-magnets, then we have a retardation in the process, due to the coercive force of the iron—a magnetic inertia which consumes time and delays the action sufficiently to permit its observation. Therefore, investigation with magnets would seem to be more promising than with currents alone. About a year and a half ago, while studying the effects of armatures of various kinds on the distribution of the force in U magnets, I detected an unmistakable motion of lines of force, which I subsequently investigated and verified fully. I found that on approaching an armature to the poles of the magnet, those lines which cross to the other pole at points on the sides (supposing the poles turned upwards) followed the substance of the magnet upward further, and crossed to the other arm at a point much nearer the poles, and thus crept up, nearer and nearer the poles, until the armature arrived at contact. With the recession of the armature from the poles, the lines fell down the sides from the poles and crossed over at lower points until their original place was resumed. It may be said here incidentally that these motions of the lines of force can account satisfactorily for the currents produced by motions of the armatures of electro-magnets observed by Lord Elphinstone and Professor Vincent.

From these observations, and from other facts which I had previously studied out, I concluded that when a magnet is demagnetising, the lines of force fall down the sides (in U magnets) and contract to the base. When the first paper of Lord Elphinstone and Professor Vincent was received in America, I saw the application of this theory as an explaining factor, and in a letter (December 15th, 1879) to an eminent American scientist, I mentioned it as an argument bearing on a discussion then open between us. A partial quotation will be of interest in this connection. "As to the reason why the magnetic force disappears so rapidly without the armature, my opinion is this—when the armature is removed sufficiently away to overcome the existing tension, by breaking the circuit, the lines of force rebound back in the manner explained in my paper, and undergo a reconstructive process—*i.e.*, the lines of force which went up to the end of one pole through the armature down the other pole now spring out from all points, and endeavour by a circuitous route to re-establish circular connection, and then takes place that *passive* action of shortening which has so often been mistaken for the *active* process, precisely in the same manner that the magnetic field around a linear conductor disappears on breaking the current. The reason why the (ethereal?) medium does not perform the same function as the armature is that, being *diamagnetic*, it possesses no coercive power at all; and instead of gathering the lines of force together, tends to part them, or make them self-repellent, while *paramagnetic* substances like iron concentrate lines of force. As a practical fact it is notable that the size and surface contact of an armature modify considerably its keeping powers on a permanent U magnet."

adduce consists in a comparison between the prices of two watches manufactured by machinery in America, where, as is generally admitted, its use has been pushed as far as anywhere. They are movements of the same size; the cheaper, approximately adjusted for heat and cold, costs about £12, and the other, more highly finished and adjusted, is quoted at nearly £50, more than four times the price of the first, and yet, to an ordinary observer, such difference as there is would be of comparatively little moment. One may safely assume then that at least half the price of the higher class watch has been on account of skilled labour. Thus we have no present need to complain that any system has proved itself to be superior to that adopted in this country, so far as regards the best work, and what is now principally needed is that the number of competent workmen should be augmented. Machine work need not, then, degrade the manual skill of our artisans, and the fear that it will necessarily cause the English watch to become less artistic than at present is equally unfounded. The fact that a particular machine does not produce artistic work is, of itself, no evidence against machinery being able to do so, and there are abundant specimens on the table to show that graceful forms can be secured by such means. Moreover, in the cheapest watch, what is wanted is soundness and good timekeeping, and, if needful, hand labour might be relied on for modifying the form according to taste in the higher grades. But the rapid growth of the production of foreign countries, as compared with our own, if it means anything, must be taken as evidence that the English system of manufacture is not adapted to the cheaper class of watch. If it were, it would be simply impossible that more than a quarter of a million of foreign-made watches should be annually required to satisfy the demands of the home market.

But how to popularise the use of machinery is a very difficult question. The factory system would certainly not be welcomed in Clerkenwell. And it may well be doubted whether its introduction would be advisable; the English system has so long consisted in a certain degree of isolation of various branches that efforts should rather be directed towards the improvement of this system, and the setting of it on a more satisfactory footing. Let Prescot retain the movement-making, Coventry the case-making, in addition to its own individual trade of watchmaking, Clerkenwell the finishing, escapement-making, &c., but if the trade is to continue a trade, these several branches must work more into each others' hands. It is absurd that one man should systematically be called upon to undo the work of his predecessor, when by proper organisation all such contradiction might easily be avoided. In a watch factory each man, of course, works to a template, and it is surprising that there should be any occasion to advocate its use at the present day, in any of the mechanical arts that involve the production of a number of identical pieces. It is difficult to see why a common standard should not be introduced in the watch trade, and its adoption would constitute a very important step in adapting the English system of manufacture to modern requirements.

ELECTRO-MASSAGE.

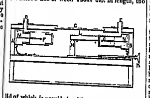
A LARGE portion of electrical treatment that hitherto could only be carried out by specialists by using elaborate apparatus, by the proper use of a new mode of treatment, by employing the apparatus shown in the engraving, can be

intrusted to the hands of those who are not so skilled. By means of this simple machine the manipulator transfers the mechanical motion used in rubbing the patient into an electrical current, and the current as it is generated is transmitted through the part while being rubbed, and it fulfils the requirements of a treatment including rubbing, kneading, pounding, flexing, etc., combined with the application of the electric current. The instrument consists of a metallic roller covered with chamois leather or other suitable material, an electro-magnet, and a permanent magnet set in a strong frame, which holds the instrument together.

The roller, besides acting as the driving-wheel of the machine, is so arranged that it also acts as one of the electrodes by which the current is transmitted, and is connected by gearing with the electro-magnet so as to cause the poles of the latter to revolve opposite those of the permanent magnet which forms the handle of the instrument. Each revolution of the roller produces twenty-five revolutions of the electro-magnet, which is magnetised and demagnetised at each revolution, and thus induces a current of electricity which is ample for all purposes for which it is intended. The circuit is completed by connecting any required electrode by the binding-post at the side of the instrument, the roller acting as the other electrode; both are brought into contact with the surface of the body of the patient, and as the roller is moved about over the surface, the current is established and transmitted through the part over which the roller is made to revolve. This machine includes in itself an electric generator, a rubber, kneader, a manipulator, and a set of electrodes, all in one. Any person ordinary intelligence can be taught to use it under the direction of the attending physician. It is portable, being quite capable of being carried in an overcoat pocket. The inventor finds in practice that it has far exceeded his expectations, inasmuch as by its use he gets greater tonic effects than from the employment of both faradism and massage separately. It fulfils most of the requirements of the induction current in general practice and every-day cases. As the current is generated by motion, no acids or liquids of any kind are necessary. The instrument is at all times ready for use, a matter that will be appreciated by all who use electricity. This treatment has been used with great success in cases of nervous exhaustion, debility, neuralgia, rheumatism, paralysis, etc., and we are informed that it is recommended by the medical profession generally. This invention has recently been patented by Dr. John Butler, of New York City.—*Scientific American.*

LIVEING'S INSTRUMENT FOR DETECTING INFLAMMABLE GAS IN MINES.

THE following description of Mr. Liveing's instrument for detecting and measuring inflammable gas in mines is taken from the pamphlet issued by the author, which can be had of Messrs. Clark, Muirhead, and Co., Regency-street, Westminster. The principle on which the instrument is based may be thus described:—A mixture of marsh-gas (fire-damp) and air in which the marsh-gas forms less than five per cent. by volume, is not explosive*, or capable of continuing its own combustion (starting at ordinary temperatures and pressures), simply because the heating-value of the marsh-gas is insufficient to raise the large excess of atmospheric air to the necessary ignition-temperature. If, however, such a mixture is exposed to some sufficiently heated object, especially if that object is platinum, it will burn in its immediate contact and neighbourhood, and in so doing add materially to the temperature of the object, and the more so the larger the percentage of gas present. To apply this principle to the detection and measurement of gas in mines, the arrangement shown in the sectional diagram is employed. A B is a narrow box of wood about 8in. in length, the



lid of which is provided with a narrow glass window, C, and also with two short entrance tubes, D and E. At each end of this box is arranged a fine spiral of platinum wire, F and G; through these a current from a small magneto-electrical machine, contained in the base of the instrument, is made to circulate; both wires being in the same circuit, and offering equal resistance to the current and cooling surfaces, become equally heated on turning the machine. One of these spirals is inclosed in a small tube having a glass end and containing pure air; the other is exposed within a small cylinder of wire gauze (also with a glass end) to whatever gaseous mixture is drawn within the instrument for examination. So long as the air examined is free from combustible gas or matter, the two spirals glow with an equal brilliancy, but if the air contain any amount above 1-400 of its volume of marsh-gas, the exposed spiral increases in brilliancy, and the more so the nearer the percentage approaches the explosive proportion; and this difference of brilliancy becomes a very delicate test of the presence of gas, as well as a means of determining the percentage present.

To measure the difference of brilliancy, a simple form of photometer is provided, consisting of a small wedge-shaped screen, H, the two surfaces of which are illuminated, the one by the covered platinum spiral, and the other by the exposed one. The two surfaces are viewed through the window C in the lid, and when the instrument is employed for measuring purposes the screen is moved towards the covered spiral by the slide-rod, K, until its surfaces appear equally illuminated in the particular gaseous mixture under examination. Within the box, in close proximity to the sliding screen, is placed a scale, L, which gives at once the percentage of gas due to any given position of the screen. This scale is rendered visible by the light from the platinum spirals, which is found sufficient for the purpose. The following table shows the difference of brilliancy due to stated percentages of marsh-gas:—

Percentage of CH_4.	Relative Illuminating Power of Spirals.	
	Covered Spiral.	Exposed Spiral.
Pure Air	1	1·
¼ per cent. marsh-gas	1	1·21
½ ,, ,,	1	1·65
1 ,, ,,	1	2·78
2 ,, ,,	1	5·1
3 ,, ,,	1	22·0
4 ,, ,,	1	61·0

This table will give some idea of the delicacy and striking character of the test; for it will be seen that in the presence of two per cent. of gas (the limit detectable with the lamp), the exposed spiral is five times as bright as the covered one, and that before the explosive proportion is reached it becomes sixty to seventy times as brilliant.

In considering the above table it should be borne in mind that the actual results depend much upon the size of the wire, the proportion of the spiral, and other conditions, and can only be determined by actual trial in known mixtures. It is a point worthy of note, that the rate at which the handle is turned within reasonable limits does not sensibly affect the ratio of brilliancy so long as the exposed wire is heated to tolerable redness. Now with regard to the practical use of the instrument. In modern systems of colliery ventilation the main current of air that descends the downcast shaft is soon sub-divided into separate currents or "splits" as they are called; these passing along the principal travelling ways are conveyed to the different districts where the men are working, and after ventilating a certain number of working places and becoming more or less contaminated with the gas that is there evolved from the freshly-exposed surface of the coal, are carried by air-ways known as "returns" to the upcast shaft, often skirting in this part of their course large areas of broken ground (or goaf) where the coal has been more or less perfectly removed.

It is for the examination of the air passing in these different returns that this instrument is particularly valuable, as it at once enables a colliery manager to determine the quantity of gas evolved in the different working districts, and thus to regulate the proportion of his various currents of air, so as to make the best use of the given ventilating power that he has at his disposal, and not have some of his air-ways considerably contaminated with gas whilst others are practically free (a condition by no means unusual). Again, if a regular account of the observed percentages of gas be kept, the quantity of air passing and the barometric pressure being also noted, it will soon become evident within what limits the gas usually varies; and should at any time an abnormal increase be observed, it will be desirable to follow up the return until the source is ascertained and the necessary precautions taken, the effect of the possible presence of coal-dust being always borne in mind.

The instrument thus employed, and the results carefully considered, cannot fail to be of assistance in laying out and regulating the ventilation of collieries. There is, however, another, and perhaps more urgent requirement, which it is hoped this instrument will also meet. In every colliery where gas is liable to be found, the working places and travelling ways leading to them are systematically tested for gas every morning before the men are permitted to go to work; and so also where the hardness of the coal necessitates the use of powder,

* This is not strictly true of some varieties of fire-damp, which appear to possess a greater heating value than ordinary marsh-gas. (See Prof. Abel's report, in which smaller percentages are shown to be explosive.)

or upwards of 10,000,000 less than the number passed over the wires of this country.

In Germany, with a population of 42,700,000, the number of telegraphic despatches was barely 100,000 more than those of France, or 14,540,000.

The only cases in which the proportionate number of messages is at all larger than in Great Britain are those of Belgium and Switzerland.

In neither of these States does the total number of messages amount to 1 per head of the population, and in Belgium the number forwarded is even closer to the British ratio as compared with population. But both these countries derive an exceptional advantage from the number of foreign telegrams passing through them, and not, as it were, resting within their borders. English messages are not swollen to any appreciable extent from this cause. Switzerland, moreover, has its native business largely increased by the host of locomotive and telegraphing foreigners annually attracted to the playground of Europe. Hence it may be fairly said that England is decidedly ahead of continental Europe in the matter of telegraphic employment.

During the present year arrangements have been made for the erection of over 5,000 miles of new wire, intended to meet the demands upon the system made by the prospect of reviving trade. The cost will not add to capital sunk in telegraphs, but will be all charged to the revenue of the Department.

For two or three years past, owing to the commercial stagnation that has prevailed, the rate at which the use of the telegraph has progressed has been but slight.

As regards railway telegraphs there are at present 14,889 miles of poles, 62,099 miles of wires, 13,128 speaking instruments, 22,411 block instruments, and 11,308 semaphore repeaters. All these being used for working the "block" system.

In the discussion which followed the reading of the paper

SIR CHARLES BRIGHT, late chief engineer to the British and Irish Magnetic Telegraph Company, said that he considered that the progress that had been made in telegraphy under Government management was highly creditable. As regards Sounders, he pointed out that his Bell system was entirely one of sound, and was exclusively used by the company of which he was engineer. He hoped that at some future date statistics of foreign messages would be forthcoming.

MAJOR WEBBER pointed out that Mr. Graves' paper was the first of the kind that had been read before the Society; the period chosen was particularly a happy one, inasmuch as it was coincident with the growth of the Society of Telegraph Engineers. He expressed a hope that a 6d. rate for telegrams would shortly be introduced.

Mr. C. E. SPAGNOLETTI, in seconding a vote of thanks, complimented Mr. Graves on the paper he had read, which must have involved a great deal of trouble to get up.

Mr. ROBERT GRAY said that as regards the cheapening of telegrams, the traffic on the Marseilles-Algiers cable, which was formerly transmitted at the rate of 2d. per word, could now be sent for 1d. per word, two cables being used for the purpose. The increase in traffic consequent on the reduced rate had quite paid for the new cable.

The PRESIDENT having made some concluding remarks, the meeting adjourned.

AT an extraordinary general meeting of the Society held June 3rd, Mr. W. H. PREECE, President, in the

The Sun.

TUESDAY, AUGUST 2, 1881.

DISCOVERING THE BULLET.

THE MAGNET PROVING THE CORRECTNESS OF DR. BLISS'S DIAGNOSIS.

Interesting Experiments to Definitely Locate the Bullet in the President's Body—An Electric Apparatus Unerringly Telling the Secret Through a Telephone.

WASHINGTON, Aug. 1.—The magnet has discovered the bullet in the President's body, and the telephone announced that discovery so accurately that Dr. Agnew can, by one quick cut with the lancet, reach the missile. The experiments that resulted in revealing the hiding place of the bullet were made this morning. The President was found to be in good condition for the tests after the morning examination. Prof. Bell and his assistant, Mr. Tainter, were in the consultation room, and when Dr. Agnew told them that they were prepared to begin the search, Prof. Bell made ready his delicate instrument. The coils of wire were charged with the electric current, and the telephonic attachment was applied. Through the mysterious relation that is established between the electro-magnet and metallic substances, as well as the equally mysterious relation that electricity and harmony bear toward each other, it was proposed to fix the spot where lay buried a leaden ball in the flesh of the President. The science of surgery had been unable to locate the ball. The physicians have inclined to the opinion that a black-and-blue spot on the abdomen indicated that the ball lay directly beneath it; but this was only a surmise. It would not be safe, were no operation necessary, to cut into the flesh at this point unless the ball was certainly to be found there. The President was bolstered up in bed, and watched every movement that was made. His eyes were constantly on the instrument. He looked curiously at it. When Mr. Bell took his place a few feet from the bedside and put the telephone to his ear, the President was intently watching him.

[illegible]

Tribune. Aug. 2. 1881.
(See Induction #12.)

Electricity was put to an entirely new purpose yesterday in determining the position of the bullet in President Garfield's body. The instrument called an induction balance, invented by Professors Bell and Tainter, seems to have done its work admirably in the first experiment. The ball is where the surgeons believed it to be, and further experiments will, it is thought, show to a fraction of an inch how far beneath the skin it lies. Its position is such that the wound can heal without danger of internal abscesses. When the patient gains strength there will probably be little trouble in extracting the ball by an incision in the wall of the abdomen. Meanwhile, we have still reason for thankfulness in the fact that the progress of the President toward recovery, though slow, is steady.

Sun. Aug. 8. 1881.

THE LOCATION OF THE BULLET.

Dr. Agnew Says that the Probe, not the Electric Balance, Gave the Information.

PHILADELPHIA, Aug. 7.—Dr. Agnew has given to the *Times* a statement regarding the location of the ball in the President's body. An examination with the probe has resulted in showing that the wound is of a far less serious nature than was for a long time supposed. It has been definitely ascertained that the cavities of the chest and abdomen were not entered, and necessarily the peritoneal membrane was not pierced, nor was the liver torn. The opening of the wound is between the tenth and eleventh ribs, four inches to the right of the spinal column, and the ball took a course almost directly downward. The bullet striking and splintering the eleventh rib, lost considerable force, and, being deflected, passed [illegible]

Some thirty years ago the remedial uses of Electricity were almost ignored by the regular Medical Profession, because unfortunately electricity was mostly in the hands of uneducated parties, who applied electric shocks in utter ignorance of the effects they were going to produce. They acted somewhat after the fashion of a surgeon, who in place of performing an operation, with full knowledge of the anatomy of the parts to be operated upon, in his ignorance plunges the knife into the body without knowing what he is going to hit. Fortunately electricity is seldom so dangerous as the knife, otherwise many fatal results would have attended its first application by the ignorant.

We had the satisfaction to furnish twenty five years ago, some of our most eminent physicians, with improved machines, for the production of temporary strong currents; among them we can name the late Dr. Valentine Mott, and Dr. W.H. Van Buren. We called attention to the fact that among other uses such applications are very beneficial in cases of paralysis, to keep up daily involuntary muscular contraction, and so prevent the atrophy of the muscles, which is the unavoidable consequence of not using them. When the cause of the paralysis is finally removed electricity has kept the muscles in good contractile condition and they are found ready for their regular functions.

Great expectations were fostered about the efficiency of Electric baths in extracting injurious substances, such as metallic poisons from the system. Theoretically it must be conceded that those expectations appear well founded, but unfortunately it must be conceded also that the expectations have rarely been realized; probably however simply by the ignorance of most of those applying them.

We say this with emphasis as in several instances, where we visited such institutions, we found the connections the inverse way, they should have been, and the electric current in place of carrying obnoxious bases out of the body and depositing them upon the copper with which the bath tub was lined, or upon the copper electrode plunged in the water, the copper was by reason of improper connections carried toward the body of the patient.

We mention this as a warning to all who use electric baths, that they should be particular not to take them except from parties well versed in electrical science.

ELECTRIC AID FOR GOLD SEEKERS.

Edison on the Chances of Finding Kyd's Treasure with an Induction Balance.

A reporter of THE SUN yesterday showed to Mr. Edison the following item:

The value of electrical inventions has received a fresh illustration in the case of the schooner Vermilion, which was wrecked in Lake Erie in 1813. The vessel was loaded with copper ingots of the value of $20,000, but her precise location far down in deep water was for thirty-four years a mystery. It remained for electricity to solve the mystery. With a newly invented electric indicator on board a cruising schooner, evidences of the proximity of submerged metal were at last obtained, and divers have begun the recovery of the valuable cargo.

"I rather think that is a made-up item," said Mr. Edison. "Some fellow has read about the induction balance used in the President's case and has gotten up the item."

"Could the induction balance be made use of for such a purpose?"

"Oh, it is quite possible. When brought near to such a mass of metal as a cargo of copper, it would indicate its presence."

"Even if it were stowed away in the hold and the timbers of the hull separated it from the induction balance?"

"Yes, I think it would."

"Then the induction balance would be a handy thing for seekers after Capt. Kyd's buried treasure to take along, so as to let them know whether they are nearing it or not?"

"Well," said Mr. Edison, laughing, "the trouble is that the induction balance simply indicates the proximity of a good electrical conductor, such as metal. Therefore, in poking around after a submerged vessel or buried object with an induction balance you would only get indications that metal was about. A good deal of metal is used in the construction of vessels, and so you would not really be certain of anything more than that there was something metallic down there. That is the reason why I think the item is an invention. If they knew the locality where the vessel was sunk they would not need to use an induction balance in searching for her exact position. A few days ago I was out at Port Huron, Mich. A vessel had sunk some seven or eight miles from there, and it could be seen plainly enough, although it was forty feet below the surface."

"Can the electric light be made use of for submarine exploration?"

"Oh, yes. I have an electric lamp made for submarine work on exhibition at Paris. The water can be lighted up as well as the air. I could lay a cable from here to Sandy Hook, with lamps about fifty feet apart and light up the whole channel."

"Would it be lighted up so that a pilot could see all the rocks and shoals?"

"Yes. He could pick his way along just as you can along the street.

AN ELECTRICAL BLOWPIPE.—The electrical blowpipe of M. Jamin, consists of a pair of carbon pencils—an electric candle, in fact—surrounded by a coil of insulated copper wire wound a few inches distant from the pencils in the plane of their axes. The current is so led that, in circulating round the coil, it will attract the electric arc formed at the lower end of the carbon pencils, and cause it to flash out almost in the form of a fish-tail gas flame. This spreading out of the arc is the special feature of the action of the apparatus. It facilitates the application of the heat of the electric arc to the fusion of refractory substances, and enables us better to take advantage of this little-used means of producing a very high temperature.

ELECTRIC FLYING MACHINE.*

The improvements recently made in electric motors have suggested to the eminent French electrician, M. Gaston Tissandier, the idea of employing these machines to propel air balloons. They can be used in connection with M. Planté's secondary couples, which store a large amount of electric energy and weigh relatively little. Such a motor possesses great advantages. There is no danger of firing the volume of hydrogen above, and it has a constant weight, there being no decrease by combustion.

In making his experiments M. Tissandier employed a small oblong balloon ending in conical points. This balloon, which is like that used by M. Giffard, is 3 m. long by 1·30 m. in diameter, and has a volume of about 2 200 liters. Inflated with pure hydrogen it has an ascensional force of 2 kilogrammes.

It is worked by a small electric motor resembling the Siemens dynamo, and weighing 220 grammes. This works a light propeller 40 inches in diameter. This motor is suspended below the balloon, and will propel the balloon for several miles with a Planté element of 220 grammes, while with a secondary couple weighing 1·300 kilogrammes the duration of its rotation is considerably increased. Under these conditions the armature turns 6·5 times a second, and acts as a propeller, giving the balloon a speed of 1 m. a second during more than 40 minutes. With two secondary elements, a propeller 60 inches in diameter can be used, which will propel the balloon at the rate of 2 m. a second during 10 minutes; and with three elements a speed of 3 m. can be obtained.

These experiments took place in the "Conservatoire des Arts et Metiers," at Paris, in a large hall, where the balloon could move freely, restrained only by a light rope dragging behind it, which served at the same time to guide and to measure its speed.

The working power of the electric motor was measured by the simple method of lifting weights. A secondary element, and afterwards two elements together, were attached to the motor, and it was found that the swiftness of the revolutions varied according to the weight lifted.

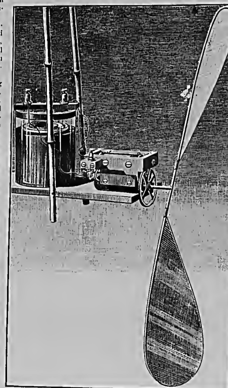
This little motor, when developing a maximum of energy with a single element, produced a force of 90 grammes at a speed of 5 revolutions a second. With two elements a speed of 12 revolutions a second was obtained and a power of 420 grammes. With three elements the power was 1 kilogramme.

In working with two elements, if the speed is reduced to 5 or 6 revolutions a second, the power is also reduced, and, on the other hand, if the speed becomes greater than that which corresponds to the maximum power, the working force is correspondingly reduced. For example, if the speed obtained is 14 or 15 revolutions a second, the power is only 375 grammes. The manner this trial balloon acted, and the speed obtained with the propeller, afford a very satisfactory outlook for aerial navigation, as it must be remembered that in balloons the surface does not increase with the volume, consequently the results obtained with larger balloons would be still more favorable.

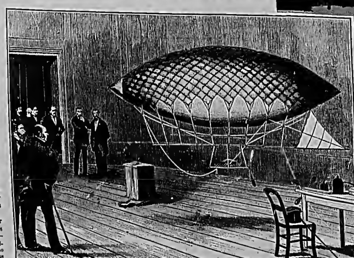
In working condition an electric motor equal to 6 horse power and weighing 3 0 kilogrammes, with 900 kilogrammes of secondary elements, would easily carry 1,200 kilogrammes when attached to a hydrogen balloon of 3,000 cubic meters, elongated in shape like those used in 1852 by M. Giffard, and in 1872 by M. Dupuy de Lôme. This balloon would be 40 m. long by 13·50 m. wide across the center, and its ascensional force would be about 3 300 kilogrammes. It would weigh, with all its accessories, 1,200 kilogrammes; so there would remain for the voyagers and for ballast over 1,000 kilogrammes. In calm weather this balloon, worked by an armature of 5 to 6 m. in diameter, would obtain a speed of 20 kilogrammes an hour, and in windy weather would be powerful enough to move out of the direct line of the air current.*

Of course, this balloon could only go for a limited time, but that could easily be decided by experiments, in which results even more favorable might be obtained by making the motor and piles especially light for this purpose.

Until now no balloon has ever been really steered, that is, has never returned to its point of departure after having navigated the atmosphere at the will of its pilot. Necessarily such voyages can only take place in calm air and during a short time; but the essential point is that they have succeeded at all; and no physicist can deny that the electric motor and the secondary piles have solved the problem of aerial navigation.



PROPELLER OF ELECTRIC FLYING MACHINE.



ELECTRIC FLYING MACHINE.

* Of course the idea of guiding balloons against strong winds belongs to Utopia; but for short voyages, such as escaping from a city during a siege, it would be very valuable to be able to steer the balloon.

Southern New Jersey Sinking.

Professor George H. Cook, State Geologist of New Jersey, concludes that the land in Cape May and Cumberland counties is gradually but certainly sinking. From knowledge now in his possession he estimates that the surface has settled about eight feet during the last hundred years. During a recent visit he declared it his intention to test the matter by placing stone posts in the ground at certain localities, a record of which should be kept so as to insure their being

Mining & Sci. Press, Aug. 28, 1880 33

AN INTENSIFIED ELECTRO-MAGNET.—Dr. Stone recently exhibited before the Physical Society a very interesting electro-magnet of novel construction, and based upon a principle which will probably be applied with advantage in the construction of electro-magnets for dynamo-electric machines and telegraphic apparatus. It is known that electro-magnets enclosed in jackets of soft iron are far more powerful than when the copper coil of wire is unenclosed. The iron jacket has the effect of exalting the magnetic power of the poles. Dr. Stone does not employ a soft iron jacket, but instead of using copper wire to wind the bobbins, he uses best charcoal annealed iron wire about one-fifth of an inch in diameter. Four wires are wound on in parallel circuits, and the current is split up among them in "multiple arc." They are insulated from each other by paraffine wax. By this felicitous arrangement the lifting power of Dr. Stone's large magnet is, with a battery of four or five Bunsen cells, increased fourfold.—*Engineering.*

English Mechanic & World of Science. Aug. 12th 1881.

A patent has lately been taken out in France, by M. Tissandier, for a balloon of elongated shape to be propelled by means of an electric motor and screw. He notices the advantages of the electric motor over a steam-engine for balloon purposes. 1. It has a constant weight, and does not disturb the conditions of equilibrium, whereas a steam-engine is always losing weight, and gas must be let off to compensate. 2. The electric motor works without fire, and so is safer (in presence of the combustible gas). True, there is a spark, but it is localised, and cannot be compared to a fireplace giving out sparks; besides it may be inclosed with metallic sheets. 3. The electric motor has great simplicity, and is easily managed. The balloon (of which M. Tissandier is having a small model made by M. Trouvé) will be worked by a very light dynamo or magneto-machine, the metallic pieces of which will be hollow. The force will be supplied by an electric accumulator made as light as possible (an ebonite or parchment-receiver containing very thin sheets of lead). Under these conditions a considerable force will be at disposal, during a time pretty short indeed, yet of sufficient length to allow of a demonstrative experiment in calm air. Should the model prove a success it will be shown at the exhibition.

Daily Graphic, Oct. 14, 1881.

AERIAL NAVIGATION.

Mr. F. W. Brearey, a member of the Aeronautical Society, read an interesting paper this week in the Birkbeck Institution, Southampton buildings, on aerial navigation, explaining, with the aid of models, the principles upon which attempts had hitherto and should in the future be made to effect artificial flight. The conclusion at which the Aeronautical Society had arrived was that flight was merely a mechanical action capable of imitation, that it was unassisted by air cells or other contrivances for effecting levity, that the balloon was incapable of being rendered useful to man as a means of locomotion except in the way of waftage, and that this mode of progression in relation to the earth was capable of being materially assisted by some method of raising or lowering the balloon at pleasure without loss of gas or ballast. After pointing out some of the conditions under which a fish moved in the water and a bird in the air, he said he was quite prepared for the discovery of some peculiar conditions attaching to the agitation of this thin medium of which we had no conception. The tenants of the air, great as was the variety in their size and form, resembled one another in possessing three important capacities, the association and proper adjustment of which constituted the property and power of flight, viz., weight, surface and force. The weight of a body was due to the action of gravity, and the problem was how so to retard or regulate the action of gravity as to cause its influence to be infinitesimally distributed. Having explained what he wished to show by projecting some peculiarly-folded pieces of paper across the theatre, he then let fall from a height a bel-shaped model, which soon, taking a curve, shot out in a nearly horizontal direction for a time. Had force, the third great principle of flight, been employed, it would have neutralized the action of gravity so long as it continued, and the flights of the models would have been prolonged. In endeavoring to estimate the proportion of plane surface to weight, so that the one might carry the other by the application of impulsive force, we were not without significant data. So varied were the forms of flight and so widely different the conditions—in some cases a heavy weight being supported by small planes or wings and in others little weights by extensive surfaces—that if ever the subject should be mastered, flight would probably be effected in more ways than one. Great weight and small surface, as the observations of M. de Lucy showed, must be accompanied by great velocity, as in the flight of the common sparrow, while with small weight and great surface, as in the butterfly tribe, a reduced velocity only was requisite. If, therefore, man could construct the necessary surface of strength sufficient to insure safety, he could certainly add, by the aid of engine-power, sufficient velocity to obtain support upon the atmosphere. Showing this by the flight of models with wing surfaces of different forms, which were propelled by the torsion of indiarubber bands, he then gave an account of experiments which had been made within the last thirty years. It was to be regretted that many were working in secret, and thus the causes of failure were not generally known. One reason for this secrecy was the fear of ridicule; another, the state of the patent laws. He had himself turned his attention to the parachute, because it was known that a surface of thirty square yards would bring a man safely to ground, and his efforts had been directed to providing a means of propulsion. He was not without hope, especially since he had held a conversation with Dr. Siemens at York, that in electricity would be found the means of supplying a force which would make it possible to transport a weight of, say, 300 pounds in the air.—*London Times.*

Electricity and Ballooning.

Soon after the announcement of Faure's new accumulator of electricity the idea was thrown out by Mr. Martin Tupper in this country that storage batteries could be employed with advantage in propelling balloons. Power and not levitation was, in Mr. Tupper's opinion, the true key to the attainment of aerial travel. French aeronauts have also given their attention to the subject, and at the recent meeting of the French Academy of Sciences M. Gaston Tissandier made a communication on it. The true solution of the problem, if it be feasible at all, appears to us to lie not in the exclusive use of levitation or electric power, but in a proper combination of both principles. This plan is that which M. Tissandier contemplates, and he points out that a propeller driven by electricity possesses advantages over other methods of movement. For example, it requires no fire, which is a dangerous element in a balloon inflated with hydrogen gas; it has a constant weight and gives off no products of combustion, and is readily manipulated.

M. Tissandier prepared a small balloon, pointed at the ends, 11 feet long by about 4½ feet in diameter. Its volume was 484 gallons, and when filled with pure hydrogen gas it had an ascending force of about 4½ pounds. A Trouvé motor of the Siemens type weighing nearly 8 ounces was fixed to the lower part of the balloon and connected to a double-bladed screw of 18 inches diameter. With the aid of a Planté secondary battery weighing nearly 3 pounds, the screw was driven at the rate of 6½ turns per second, and propelled the balloon through the air at a speed of over 8 feet per second during a space of 40 minutes. With two secondary elements weighing 1⅓ pounds, and a screw of 21 inches diameter, a speed of 6½ feet per second was maintained during 10 minutes. With three elements the speed was about 10 feet per second. M. Tissandier also measured the work done by the little dynamo-electric motor, and found it to be about 3·1 foot pounds with a single element and a speed of 5 turns per second; and with three elements it is about 7 foot pounds. He estimates that a dynamo-electric motor of 5 cwt. with 17 cwt. of secondary batteries will yield 6 horse power of work. This weight could be raised by a hydrogen charged balloon of 3,900 cubic yards volume, and similar to that employed in 1852 by M. Giffard, and in 1872 by M. Dupuy de Lôme. It would be 131 feet long by 43 feet in diameter at the middle, and its ascending force would be about 3½ tons. With all its appurtenances it would weigh from 19 cwt. to 22 cwt., and there would remain from 1 ton to 2 tons for ballast and voyagers. In calm weather it would have a speed of from 12 to 15 miles per hour, and it would be able to deviate from the line of a wind.

It is true that this result could only be obtained during a limited time, but the conditions would be greatly improved by lighter batteries and possibly by the use of M. Faure's accumulators. While upon this subject we may also mention that M. Trouvé has tried his electrically propelled boat on the upper lake of the Bois de Boulogne with a Trouvé motor and a four-bladed screw about a foot in diameter. Twelve Bunsen cells of Ruhmkorff's pattern propelled the boat, containing three persons, at a speed of 10 feet per second, but this rate fell off at the end of three hours to about 9 feet per second, and at the end of five hours to 8 feet per second.—*Engineering.*

Sept 11 1880 Sc. Am. Sup. No 245 40

NEW DIELECTRIC MACHINE.

By the Abbé Le Danteo.

Mr. Le Danteo has invented a dielectric machine which unites the chief principles of all electric machines hitherto invented, and is a great improvement upon the latest one, constructed by Mr. Carré, two of this latter kind being ingeniously connected in one of Mr. Le Dantec's. The construction of it is as follows:

(1) A plate of gum lac, B, which is rubbed by the hands, reminds us of the first electric machines invented by Otto von Guerike and Hawksbee. A rest, E, isolated by two glass posts, serves as a support for the hands, and if the person who rubs the gum-lac plate stands upon a glass stool he is positively electrified.

(2) A glass plate, A, with its rubber, D, and its iron comb, shaped like a horseshoe, as indicated in our illustration by K, reminds us of Ramsden's machine. This comb, K, which is movable around a horizontal axis, can be placed in the position, K', when it is necessary to set in motion the whole of the machine. It is connected by means of the small chain, H, with an isolated copper ball, which serves as a conductor.

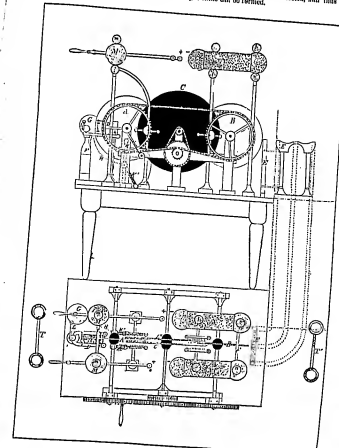
(3) The rubber, D, of the glass plate is carried by a horseshoe and isolated by three glass posts in such a manner that both kinds of electricity can be collected as in the machine of Nairne. One of the supports, F, of the rubber of the glass plate is a Leyden jar, which serves for the condensing of both kinds of electricity, as soon as its outer coating is connected with the ball, O. The electric spark springs

Dantec: Why should not this part of the plate serve to transport positive electricity, as the lower part of it serves to transport negative electricity? This thought led him to make the following improvements: First, he employed two caoutchouc plates, C and C', and, secondly, he introduced between these two plates a plate of gum lac, B, which after it is electrified by rubbing with the hands, produces on its part the same effect as the glass plate does on its. The upper half, viz., of the two caoutchouc plates, is utilized for transporting the positive electricity, the action of which is thus added to that of the glass plate in influencing the combs of the condensers, M and M', while at the same time the lower part transports negative electricity, which assists the gum-lac plate in extracting positive electricity from the combs of the conductors, N and N'.

When, after having mounted all of the above mentioned parts (each of which is a separate electrical machine), the gum-lac plate is added, then the length of the electrical spark is doubled. We have now in reality two complete new machines in juxtaposition:

1. An anterior machine composed of the plates, C, and the conductors, M and N, which utilizes the electricities on the front sides of the glass and gum-lac plates.

2. A posterior machine composed of the plate, C', and the conductors, M' and N', which utilizes the electricities on the other sides of the glass and gum-lac plates. By means of the brass beams, T and T', the first of which is fastened to the knobs, m and m', the other to the knobs, n and n', the two machines can be connected, and thus one grand machine can be formed.



NEW DIELECTRIC MACHINE.

over between the ball, O, and the bar, L, and this latter is connected with the outer coating of the Leyden jar, F, when the isolations of the rubber are no longer needed.

(4) When the glass plate has been several times revolved by means of a crank, the motion may be arrested, and the glass plate is then electrified between the two caoutchouc plates, C C'. In turning these latter plates, the united effect of two of Bertsch's machines is produced.

Thus, as above mentioned, we find united in this new apparatus the principles of all the chief electric machines hitherto invented, and Mr. Le Dantec's machine is so constructed that these principles may either be used separately or in connection.

(5) When the glass plate and the caoutchouc plates are turned at the same time, the effect is that of two of Carré's machines.

(6) The following are the advantages of Le Dantec's machine in comparison with Carré's machine. The latter had two weak points. First, if A represents the glass plate, C the gum-lac plate, and M and N the conductors of the Carré machine, then the electricity upon that side of the plate, A, which is opposite to the caoutchouc plate, C, acts only with difficulty upon the comb of the conductor, M, from which it is separated by the thickness of the glass plate, A, and the caoutchouc plate, C, together. Secondly, the negative electricity, streaming from the conductor, M, upon the plate, C, is neutralized by the comb of the conductor, N, in such a manner that the upper half of the plate, C, is in a neutral state. Now, the question occurred to Mr. Le

All these details seem more complicated in appearance than in reality, and permit a great number of interesting combinations, which are highly instructive for the study of the different effects produced by static electricity.

Explanation of the Figures of the Illustration.

A, glass plate; B, gum-lac plate; C C', caoutchouc plates; D, rubber of the glass plate, carried by a horseshoe, which is isolated by means of three glass supports, one of which is a Leyden jar. E, rest for the hands, isolated by two glass supports. F, Leyden jar, the inner coating of which is connected with the rubber, D. O, isolated metal ball, serving as a conductor for the positive electricity streaming out of the rakes, K and K', and connected with them by the little chain, ff. K K', rakes, which can either be brought into a position opposite to the glass plate, as indicated by K, or inclined downward, as shown by K'. L, movable lever, which serves for the purpose of bringing the negative electricity of the rubber, D, in communication with the positive electricity of the conductor, O. M and N, anterior machine; M' N', posterior machine; $t t'$, glass beams, which hold the system of machines together, at the same time permitting a perfect isolation of the single parts; T T', cross beams of brass, by which the anterior and the posterior machine can be united, and the one of which is fastened to the knobs, m and m', while the other is joined to the knobs, n and n'.

17

copper deposited and depositing the zinc dissolved.

If magneto-electric machines are used for producing tho electricity necessary to renew tho battery, the renowal is done nt tho expenso of motivo power. Economically produced by tho aid of powerful machines, tho electricity becomes stored up in tho liquids, regenerated to the stato of energy which is disposable and portoble. This indirect transport of electricity generated by machines would be, in most cases, more practicable and moro advantageous than the direct transmission by cables.

Actually the renewed liquids aro not employed, the new battery offering as it does a notable economy of material and labour over tho nitric acid couples. As to the industrial realisation of the process of regeneration, which should render my battery economically applicable to small electric motors and to domestic lighting, it is yet hindered by certain difficulties foreign to the art, which will, I trust, be overcome eventually.—*La Lumière Electrique.*

ELECTRIC MINE EXPLODERS.

SIEMENS' APPARATUS.

The magneto-electric exploder.

THIS apparatus (fig. 1) consists of a number of powerful *permanent* magnets, between the poles of which there is an ordinary Siemens' armature. When the armaturo rotates, its magnetism is reversed, and the alternating positive and negative currents generated are reduced to a common direction by means of a commutator, similar to that shown at *c* in fig. 3. One complete revolution of the handle causes the armaturo to revolve thirteen times, and at each turn of the armature two currents of opposite direction are induced in the wire coil, or a total of twenty-six currents for each revolution of the handle. Tho apparatus, which consists of an armature (as above described) and six permanent magnets, has been specially designed for blasting operations, in which only a small number of shots are to be exploded. It fires twelve Abel's fuses in single circuit simultaneously and with certainty. The working parts of tho exploder are inclosed in a teak-wood case, fitted with straps and two terminals for the leading wires. The terminals are short-circuited by a firing-key, which must be depressed before the current can pass into tho lino. Tho handle can bo taken off and placed in tho side of the case. Tho outer dimensions nro 10" × 7" × 7", tho total weight only 22 lbs. The length of spark which this exploder will givo is $\frac{13}{3000}$ of an inch. A general view of tho opparatus inclosed in its case ond connected to fuses placed in tho charges in n mnss of rock is shown by fig. 2.

A largor form of npparatus, with nino permanent magnots, is of tho samo construction os tho smaller one, but tho electro-motivo forco is higher, tho spark being about $\frac{18}{3000}$ of nn inch in length. This opparatus fires simultnneously nbout soventeen Abel's fuses in singlo circuit. Dimensions, 10" × 8½" × 7". Total weight 29 lbs.

The dynamo-electric mine exploder.

This instrument consists of nn electro-mognet nnd nn ordinary Siomens' armoture, which, by tho turning of n handle, is caused to revolvo between the polos of tho *electro*-magnet. The coils of tho latter oro in circuit with tho wiro of the revolving armature, ond during rotation tho residual magnetism of tho soft iron electro-magnet cores at first excites weak currents, which pass into the coils, increasing the magnetism of the core, thus inducing still stronger currents in tho armature-wire. This accumulation by mutual action goes on until the limit of magnetic saturation of tho iron cores is reached.

By tho automatic action of the machine the powerful current so produced is sent into the leading wire to the fuse. The fuse being practically either an interruption of the circuit, or a great increase in its resistonce by the interposition of a badly-conducting substance, the consequent action is that either an electric spark passes between the interrupted portions of the conductor or the piece of bad conductor is highly heated, causing ignition of the explosive substance contained in the fuse. Fig. 3 is a diagram of connections of the apparatus.

A is the revolving armature, on the axle of which is a pinion, driven by a wheel which is turned by tho handle at the end of the machine. The axle of tho driving wheel is geared into the cam wheel, S, so that the latter makes two revolutions for every revolution of the former. F F are the pole pieces of tho electro-magnets. *c* is the commutator, by means of which the currents of alternate direction generated in the armature are caused to flow only in one direction through the coils, E E, of the electro-magnets. After every revolution of S, a tooth of the lever, D, falls into a notch cut in S, and causes the end of the lever to be forced by the spring beneath it into contact with the screw, *d*, thus breaking tho short circuit hitherto existing in the instrument, and causing the current to pass to line by the terminals, *e e*, to which tho line-wire is connected, and through the fuses, *f f f*.

Theso dynamo-machines are constructed of two kinds, viz. :—

(1) The dynamo-electric *tension*-exploder, and
(2) The dynamo-electric *quantity*-exploder.

The large tension-exploder, which is the machine just described, has its coils, both of the armature and the electro-magnets, wound with fine wire to a total resistance of 2,000 to 2,500 Siemens' units in about 17,000 windings. Upon causing the armature to revolve, currents of *high electro-motive force* are generated, and an electrical spark passing between tho separated conductors in the fuse inflames tho explosivo priming. *The line wires should be connected to the terminals of the exploder directly after the machine has clicked*, that is, when tho tooth of tho lever, D, has follen into tho cam, S. Two turns of tho hnndlo oro thch required in order to develop tho full power of tho machino before tho current passes through tho fuses. Tho total weight of tho machino is about 59 lbs. Dimensions, 15" × 15" × 7".

Tho spark given by tho lorgo exploder is $\frac{380}{5000}$ of an inch in length, and tho npparatus fires simultoneously obout 50 Abel's fuses in singlo circuit.

The small tension-exploder is of tho samo construction ns tho lorgo one, but weighs only 35 lbs. ; it is placed in n leather knopsack for transport. Tho spark given by tho smoll exploder is $\frac{180}{5000}$ of on inch in length. This npparatus fires simultoneously

about 30 Abel's fuses in single circuit. Dimensions, 12" × 11" × 6".

The large quantity-exploder is similar in construction to the tension-exploder, except that the cam, B, and short circuiting lever, D, are omitted, and the coils of the armature and electro-magnets are wound with wire of large diameter to a total resistance of 8 to 10 units in about 2,000 windings. The electric current is, after a few turns of the handle, sent into the line wire *by pressing down a firing-key at the top of the instrument.* The current then passes continuously into line until it is sufficiently powerful to heat the bridge-wire in the fuse and cause ignition of the explosive priming. Electric currents possessing *great heating power*, but of *small electro-motive force*, are generated by this machine.

Dynamo-electric quantity-exploders are also made with an automatic firing lever, similar to that in the tension-exploders, in place of the above-mentioned firing-key.

The standard of efficiency for these machines is the fusing of a quarter of an inch of iridio-platinum wire of 0·0015 inch diameter, weighing 0·45 grain per yard, through a line resistance of 70 Siemens' units. The weight of the exploder is 71 lbs. Dimensions, 15" × 15" × 7". With short leading-wires this exploder heats 11 inches of iridio-platinum wire of 0·0015 inch diameter, which is equal to about 44 Service Detonators, No. 13.

(To be continued.)

SOME RECENT ELECTRICAL "NOVELTIES."

Electrician Aug 14/1880

It is always curious and sometimes surprising to find how early the idea of a recent invention has been mooted or its principle propounded by some other mind which lived before the time was ripe for the realisation of its schemes. "Nothing new under the sun" is a proverb to which these inventive times is ever giving proof. Edison's "Ore Separator" is a contrivance which has been again and again shown to be no novelty, but few are aware how old it really is—at least, in idea. It actually belongs to the last century; and, for aught that we know, may have entered into the idle dreams of Tubal Cain. In an English patent of date June 19, 1792, No. 1,891, William Fullarton, of Ayr, in Scotland, describes a new process for "separating iron from iron stones and other ores of that metal, of smelting it into the state of pig or cast iron, and of reducing or refining it into the state of malleable or forged iron." The patent was granted in the old style by King George III. for "His Kingdom of Great Britain, called England, His Dominion of Wales, and Town of Berwick-upon-Tweed, and also His Plantations abroad." That is a long time ago, but not before "telegraphs were thought about," for Charles Marshall, writing from the same district in Scotland, had long before (in 1753) suggested the principle of the electric telegraph; and Lesage, in 1774 had actually operated a frictional telegraph of the kind planned by Marshall.

Fullarton's patent goes on to describe the method of ore separation adopted by him. This consisted in crushing the iron ore by grinders, stamps, or mills worked by hand, horse, steam, water, wind, or other power, and, in the next place, of separating all "earthly, (*sic*) impure, and extraneous matters from the metallic particles by all or any of the following operations, namely, by washing, levigating, buddling, winnowing, and by the application of magnetic attraction, according to the nature and qualities of the different stones and ores." The materials thus purified are put into the furnace and smelted.

The electrical railway of Dr. Werner Siemens finds a forerunner in the "dynamic traveller" of Henry Pinkus, patented on March 1, 1834, No. 6,570, for the propulsion of vessels, carriages, &c., on canals, railways, or common roads. This invention relates to a pneumatic railway in which magnetic attraction may be employed, and which may either form "a complete system of railway in itself," or be applied to common railways or canals.

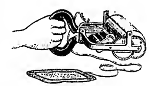
An extended tunnel, tube, pipe, or conduit is laid down, which contains a piston. On one side of the piston the air is exhausted from the tube by suitable stationary engines and pumps at suitable distances along the line. To the piston is attached "a vehicle or machine," called "the dynamic traveller," which is in connection with a car on the outside of the tube, called "the governor," to which the carriages to be propelled are attached. In the pneumatic railway itself the rails are cast on the sides of the tubes; but in its application to existing railways or canals the tube is laid down between the rails, or at the margin of the canal. The connection between the dynamic traveller and the governor is made either by means of a longitudinal "pneumatic valve," through which a vertical wire rises, or by magnetic attraction. To apply magnetic attraction effectively, the dynamic traveller carries a frame of horseshoe magnets, set transversely, with their poles placed as near to the under surface of the tube as possible. A similar combination of similar magnets inverted is attached or suspended under the body of the governor, and in order to enable the space between the poles of the magnets in the two frames to be as small as possible, the upper part of the tube has a copper plate fitted air-tight into the opening instead of a valve. In the dynamic traveller soft iron may be used instead of magnets, and electro-magnets may be used.

As regards the production of motive power by electricity, we have the patent of Miles Berry, a communication from Edwin Williams on behalf of Thomas Davenport, dated June 6, 1837, No. 7,386. This invention describes a means of obtaining rotary power by "galvanic" magnets alone, or "galvanic" magnets in combination with "permanent" magnets. The device in question consists of a number of electro-magnets fixed radially on a rotating shaft, and segmental permanent magnets, or electro-magnets, fixed to the frame supporting the rotating shaft. The motion of the rotating magnets is made to take place by the attraction of their poles towards the poles of the fixed magnets of opposite name. To effect this the rotating electro-magnets are made to change their polarity at proper times by the motion of plates (connected to the circuit of the electro-magnets) against segmental plates, corresponding in number and position to the number and position of fixed segmental magnets, which segmental plates are connected in a suitable manner with the poles of a galvanic battery.

English Mechanic & World of Science August 5th 1887.

ELECTRO-MASSAGE.

A LARGE portion of electrical treatment that hitherto could only be carried out by specialists by using elaborate apparatus, by the proper use of a new mode of treatment, by employing the apparatus shown in the engraving, can be



intrusted to the hands of those who are not so skilled. By means of this simple machine the manipulator transfers the mechanical motion used in rubbing the patient into an electrical current, and the current as it is generated is transmitted through the part while being rubbed, and it fulfils the requirements of a treatment including rubbing, kneading, pounding, flexing, etc., combined with the application of the electric current. The instrument consists of a metallic roller covered with chamois leather or other suitable material, an electro-magnet, and a permanent magnet set in a strong frame, which holds the instrument together. The roller, besides acting as the driving-wheel of the machine, is so arranged that it also acts as one of the electrodes by which the current is transmitted, and is connected by gearing with the electro-magnet so as to cause the poles of the latter to revolve opposite those of the permanent magnet which forms the handle of the instrument. Each revolution of the roller produces twenty-five revolutions of the electro-magnet, which is magnetised and demagnetised at each revolution, and thus induces a current of electricity which is ample for all purposes for which it is intended. The circuit is completed by connecting any required electrode by the binding-post at the side of the instrument, the roller acting as the other electrode; both are brought into contact with the surface of the body of the patient, and as the roller is moved about over the surface, the current is established and transmitted through the part over which the roller is made to revolve. This machine includes in itself an electric generator, a rubber, kneader, a manipulator, and a set of electrodes, all in one. Any person of ordinary intelligence can be taught to use it under the direction of the attending physician. It is portable, being quite capable of being carried in an overcoat pocket. The inventor finds in practice that it has far exceeded his expectations, inasmuch as by its use he gets greater tonic effects than from the employment of both faradism and massage separately. It fulfils most of the requirements of the induction current in general practice and every-day cases. As the current is generated by motion, no acids or liquids of any kind are necessary. The instrument is at all times ready for use, a matter that will be appreciated by all who use electricity. This treatment has been used with great success in cases of nervous exhaustion, debility, neuralgia, rheumatism, paralysis, etc., and we are informed that it is recommended by the medical profession generally. This invention has recently been patented by Dr. John Butler, of New York City.—*Scientific American.*

DE LOCHT'S PANTELEPHONE.

21

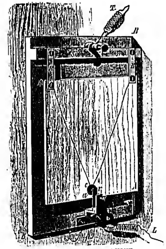
Leon de Locht, Mining Engineer and Professor at the College of Mining, Mont St. Martin 40, Liege, Belgium, after several years' experimenting with a view of overcoming the defects of the best telephones in use, and after the invention of one or two forms of apparatus, which have been the subject of patents in various countries, has finally perfected an instrument which he calls the pantelephone.

This apparatus is a microphonic transmitter which is sensitive to sonorous vibrations emanating at a great distance. It is capable of transmitting words spoken at forty-five feet from the apparatus to a distance of several miles through the medium of receiving telephones. The pantelephone, which is extremely simple, is composed essentially of a movable plate carrying a carbon contact, which presses against a disk of carbon or metal—silver or platinum.

Referring to the accompanying cut, the plate is seen figured at AA. It may be of aluminum, sheet iron, steel, brass, mica, cork, or of any substance whatever that is capable of being formed into plates of large superficial area, while at the same time possessing the requisite amount of lightness. It is preferable that its form should be rectangular, fifteen centimeters square in size, and, when made of metal, two to three tenths of a millimeter in thickness. It should be as inflexible as possible, and not liable to bend out of shape through the influences of temperature and humidity. It is suspended by two small very flexible steel springs, R R, from a support, S, which is perfectly straight and stands out from the fixed plate, B B, forming the framework of the apparatus. To the middle of the lower end of the plate is riveted or soldered a small carbon disk, *c*, which, when the apparatus is in a vertical position, rests against a small piece of silver or platinum fastened to the end of a short and somewhat inflexible spring, *r*, the latter being fixed by means of a screw, *e*, to the copper support, *b b*. By means of a thumb screw, V, passing through the support, the contact of the carbon, *c*, with the piece, *a*, may be regulated at pleasure.

The pantelephone is placed in the circuit of a voltaic pile in such a way, for example, that the current entering at L, proceeds to the support, *b b*, and from thence through the spring, *r*, to the contact, *a*, then to the carbon, *c*, and through the plate, A A, to the springs, R R, and leaves the apparatus at T.

There are other and secondary details of construction, by means of which the inventor is enabled to so regulate the apparatus as to insure of the greatest sensitiveness and of the best possible performance. There are certain arrangements employed, too, to deaden and stop all noises which might arise from tremors of the earth, or from the shaking of the wall to which the apparatus is attached. It is claimed that the pantelephone, when once properly regulated, is not liable to get out of order; and, moreover, that the expense



DE LOCHT'S PANTELEPHONE.

attending the use of the system is insignificant, since the apparatus under pr r conditions requires for its making only the electromotive force of a single voltaic couple. The instrument transmits all sounds, articulate or inarticulate, which reach it, through the medium of either solids or the air. It is inclosed in a box (which may be made as ornamental as desired) in such a way that its sensitiveness to sonorous vibrations is in no way impaired.

24

AT A FLASH.

Lighting the Street Lamps of Salem by Electricity.

The Bancroft Lamp-Lighter a Success.

Exhibition of its Working Last Evening.

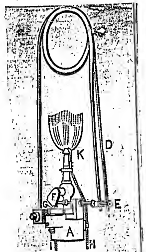
One of the most ingenious and simple contrivances for lighting and extinguishing street lamps was shown in Salem last evening to a number of gentlemen connected with the Boston and Salem press. It is the invention of Mr. George D. Bancroft, well known to the newspaper fraternity of this section of the state, having been connected with the HERALD and other newspapers for some years. The visitors were met at the depot and conveyed to the Essex House, where refreshments were provided. Then they took a barge and visited the circuits where the apparatus was in operation. There are at present three circuits attached to the main office, with 43 lamps in their lines. The first visit was made to the third circuit, which embraces a portion of Bridge, Webb, Marlboro and other streets in their vicinity, and at present has ... lamps attached. The second circuit was next visited. This embraces the ... portion of Bridge, Winter, Pleasant, Pickman, Milk and Andrew, and has 15 lamps attached. It is intended to extend this circuit east of Andrews street. The first circuit was the last visited. This embraces a portion of Bridge, St. Peter's, Brown, Newbury, Forester and Pleasant streets, and is to be extended around the Common. In these three circuits there are now laid about three miles of wire. When the visitors arrived at the third circuit they halted at the corner of Bridge and Winter streets, and witnessed the lighting of the lamps on the circuit. When the time came to light the third circuit every lamp in the circuit leaped instantly into light, as if by a magic touch. The same operation was witnessed in the other two circuits. There was no hitch, no lighting of this and leaving the other dark, but

ALL BLOOMED OUT TOGETHER,

like flowers of the nether world. The length of wire and the power used in these three circuits were sufficient to light 150 lamps. On Washington street, in Boston, from Haymarket square to Boylston street alone, there are 60 lamps, and this is only about one-fourth of the distance covered by the three circuits in Salem. After viewing the lighting of the lamps, the party went to the main office on Winter street, where Mr. Bancroft showed the party several lights in a circuit, and gave a clear explanation of the operation of his machine. The office, by the way, adjoins the office of the lamp department, to which it will soon be removed. Mr. Bancroft has been at work on his invention some three or four years, and has lately succeeded in so simplifying and perfecting it that it will now, as has been amply shown, bear the test of utility. A company to extend the usefulness of this patent was formed in Boston some six months ago with Mr. George Monroe Endicott as president, and Mr. George Fred Williams as treasurer. The company is chartered by the name of the "Thermo and Electric Gas Lighting Company," and its office is in Boston. The lighting apparatus, as explained by Mr. Bancroft, is a simple affair, of unusually solid construction and great compactness. There are but few moving parts about it; no delicate mechanism to become deranged and no bulky shell or box to intercept the light rays. It is also of

INEXPENSIVE CONSTRUCTION,

being largely made of iron castings. Its composition is mainly the iron cylindrical magnet A, its armature B, the thermal arch D, the stopcock and its lever F. The arrangement of these parts is very clearly shown in the following engraving:



A—Magnet.
B—Armature.
D—Arch.
E—Connecting rod.
F—Stopcock.
H and I—Line wires.
K—Igniting loop.

The arch is composed of a steel rod brazed to a square bar of brass and bent into the form shown above. One end is attached firmly to the arm under the letter G and the other moves loosely over the outer end of the connecting rod E, on which its travel is limited by check nuts shown on either side. The middle of the bar stands directly over the flame, and when the gas is lighted is, of course, heated to a higher temperature. When this takes place, the brass expanding much faster than the steel, which forms the outer surface of the composite bar, the whole expands as shown by the dotted lines. Now, assuming the lamp to be lighted and everything in the position figured in the cut, it will be seen that the arch immediately expands and, exerting its outward force on the stopcock through the connecting rod, and the lever F, would soon shut off the flow of gas. This, however, is prevented from being by the stud, or detent, G, on the top of the armature, which engages in a notch at one side of the lever. Now, as the armature is thrown up by a spring, it will be seen that the lever is firmly locked in the position shown, and there it must remain until released by

A CURRENT OF ELECTRICITY.

All the time the arch is expanding and storing up power, ready to be used in extinguishing. Now it should be understood that within the magnet is a helix of copper wire, one end of which is shown at I, and the other is carried up to the top of the apparatus, where it is affixed to a loop of platinum or other wire of high electrical resistance. The other end of the loop, K, is coupled to the line wire H. Now, when a current of electricity is sent through the apparatus, the armature is drawn down; the stud or detent is disengaged from the lever, and the end of the arch flies out, pulling the lever over, and so, closing the cock, shuts off the gas. Of course, the flame is extinguished, and at once the arch begins to contract, and would, were the current kept on, soon open the cock again; but, to prevent this, the current is soon broken and the armature is thrown up by its spring. This allows the detent to engage in a notch on the opposite side of the lever from that in which it was caught before. This locks the cock in its closed position, where it remains till it is desired to light again. This is accomplished after giving the arch a short time to cool, when its pressure is inward instead of outward. Then, by closing the circuit, the armature is drawn down, the cock flies open and the escaping gas, coming in contact with the heated platinum, is at once ignited. By these means the actual labor of the opening and closing the cocks is accomplished by the heat evolved by the burning gas, and it only remains for the current to release the power stored in the arch and heat the igniting wire.

The plant used by the Thermo and Electric Gas Lighting Company consists of a dynamo-electric machine, a mechanical generator of electricity, wires radiating from the central station at which the dynamo is located, and one of its patent "fixtures" at each lamp-post.

THE WIRES ARE INSULATED

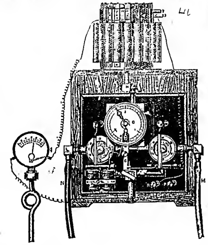
with a compound largely made up of gutta percha, and are buried under the pavements of the streets through which they pass, and each is carried up through the lamp post on its line, and makes in itself a complete circuit. Every lamp-post fixture works in unison with all its fellows on the same circuit, so that each group is lighted or extinguished as a whole. At the central office there is a switch connected with the dynamo machine, and, by means of this, the current is successively applied to each of the circuits. Usually only a fraction of a second is required to light any one circuit, but, as air is liable to escape from the burners before the inflammable gas finds its way out, it is customary to maintain the current for a moment so as to insure ignition. This is, however, a matter entirely within the control of the operator, as was proved by the exhibition of last evening. The invention seems to be in every way a superior one, and cannot fail to commend itself. Indeed, so many features of superiority are apparent in this new lamplighter that there can be no doubt of its desirability wherever gas is used for street-lighting on any considerable scale. To show how wasteful our present system in Boston is, it is only necessary to say that the cost of lamp lighters to the city is $60,000 annually, while it is estimated that the amount of gas unnecessarily consumed in consequence of our present system of lamp-lighting is at least $40,000 more a year, or a total expenditure of $100,000 by the present system.

The affair last evening was wound up by a very finely catered set-down at the Essex House in Salem, after which the Boston men took the 8 o'clock train to the Hub, with automatic lamp-lighter on the brain, for the time being.

25

ELECTRIC TEMPERATURE REGULATOR.

There are numerous chemical and other processes which require a continued maintenance of an equable temperature. A familiar illustration of this is the equable temperature required by manufacturing dentists in vulcanising the caoutchouc palates for false teeth. For this it is necessary that the pressure, which is proportional to the temperature, should sometimes be the same for several hours, and this cannot be accurately maintained, except by simply watching the pressure gauge attached to the digestor or closed vessel in which the caoutchouc is placed. This watching occupies so much time that, except where assistants can be deputed specially to the work, it is often but indifferently performed, and though the vulcanite is rendered inferior for the purpose if subjected to great range of temperature it is nevertheless used. For this purpose, then, in particular, an automatic temperature regulator is essential, and such an apparatus has been invented and patented in this country by Mr. Joseph Davidson of Berlin, who is represented in this country by Mr. H. Pischon, Metropolitan Chambers, New Broad-street. The principle of the apparatus consists in the control of the gas flame, by which the closed vessel is heated, by means of an electro-magnet, which is put in or out of action by a pressure gauge, when the pressure is above or below the desired limit. For this purpose the gas supply pipe has a valve which is connected to the



armature of an electro-magnet, so that when the latter is in action it holds the valve open against the action of a spring which tends to close the valve. One terminal of the coil of the electro-magnet is connected to the ordinary pointer of a pressure gauge, which communicates with the interior of the vulcanising vessel. The other terminal is connected to a second pointer, which is kept in electrical contact with the first pointer by the action of a spring until this moves beyond the point at which it indicates the maximum pressure, at which point is a stop adjusted by a knob outside the pressure gauge glass, and arranged so that it prevents the second pointer from following the first beyond that point. The two pointers being thus separated, the circuit is interrupted, thereby stopping the action of the magnet, which thus allows the valve to close. When this is effected, a by-pass with regulating cock allows sufficient gas to pass to the burner to prevent it from being entirely extinguished. On the pressure being reduced the first pointer of the gauge in receding comes in contact with the second one again, thus re-establishing the electric circuit, and effecting the opening of the supply valve. Within the range of about one degree the temperature is constantly maintained. The gas supply has a second shut off valve, which is kept open against the action of a spring by a detent connected to a clock, and so arranged that when the clock has been in motion for a determined length of time, the detent is released, and allows the valve to close and cut off the gas supply entirely, thus terminating the vulcanising operation. In order that it should not be even necessary for the operator to wait until the necessary is first attained, an arrangement is made by which the regulator sets itself to work when that pressure is reached, and it then, from that moment, regulates the pressure for any duration of time for which the clock may be set. The armature of the magnet is provided with an arm that withholds the pendulum of the clock until, by the attainment of the full pressure, the action of the electro-magnet is temporarily interrupted for the first time. The armature is then raised by the spring connected to it, the pendulum released, and the clock starts, continuing for the determined duration of the process of vulcanising, at the expiration of which the clock detent allows the other spring to close the valve which it controls, and thus all gas is shut off.

The apparatus is all enclosed in a box, the glass door of which is removed in our sketch, which shows the box in section. The electric current is provided by a Noë thermo-electric battery on the top of the box, with twenty elements, and heated by a Bunsen burner, supplied by the pipe, fitted with gas cock, H. This battery, which is much used in Germany and Austria, was described in detail in *The Electrician* of the 8th May last. In the illustration B is the clock referred to, C the valve through which gas passes by the pipe N to the vulcanising vessel, M the pipe supplying the gas to the apparatus, KK the magnet, F the armature, and E the arm which holds the clock pendulum until the current is first broken. G is the clock detent which rises into the notch in the disc on the clock spindle when the determined period has passed, and thus permits the spring to close the valve D and shut off the gas. The terminals are connected with the gauge and battery as shown, and to the magnet, by means of the binding screws R and P, connected to wires behind the wood base on which the whole is mounted. The pressure gauge is shown attached to the vulcanising vessel, and as shown the adjustable stop of the gauge is set to prevent the rise of pressure above 6½ atmospheres.

Though described as employed for a special purpose the apparatus is obviously applicable as a thermo-regulator for many purposes.

In the new air thermometer of Herr Witz there is another very ingenious electrical arrangement for keeping one of the air bulbs of the apparatus at a constant temperature so as to serve for a standard and make the readings give absolute (not differential) results.

The object was to find a means of keeping the air inside the standard bulb at a practically constant temperature, and Herr Witz achieved it in the following manner. A very fine platinum wire was rolled in a helix, and introduced into the interior. It makes part of an electric circuit, which is closed by a mercurial column, movable in the recurved part of an alcohol thermometer, similar to that of Lix and Bellani. The movement of the alcohol and mercury in this auxiliary thermometer depends on the temperature of the air in the interior of the bulb where the platinum wire is fixed. One end of the mercury column is always in contact with the platinum wire; the other, on the contrary, opens or closes the circuit of a battery in advancing or receding. At the moment when the temperature of the air in the bulb decreases below a determined point the circuit closes, the current passes through the platinum wire, which is heated, then the temperature rises in the bulb, the mercury again opens the circuit, and the current is interrupted. The fixed temperature of the standard bulb is ten degrees C. higher than that of the surrounding air, and there is, therefore, a continual tendency for the hotter bulb to cool down. The result is that there is an oscillation of temperature in the standard bulb, as it is replenished with heat by the current, and parts with some of it again; but the range does not amount to more than $\frac{1}{10}$ degree C. With a steady battery the apparatus works well.

The best battery for the purpose yet tried by Herr Witz is that of Poggendorff, recently described in these columns. It is a bichromate of potash battery, as our readers will, perhaps, remember, and has an electromotive force, quantity and constancy well adapted to the regulating purpose in question. By taking care to renew every day a little of the acidulated water rendered greenish by sulphate of chromium, and to add a crystal of bichromate of potash into the porous vase, two small cells maintain the thermal regulator at 29·5° C. during a long time. Perhaps this device of Herr Witz will prove useful in other ways.

40 **A New Submarine Torpedo.**

Mining Press

The mysterious torpedo, about which so much has been said and written, which is being experimented with at Willett's Point, is entirely different from any other floating torpedo known in this country. The torpedo is the design of a Mr. Sims. It is thus described by the *American Ship:* The torpedo is of the ordinary cylindrical cigar-shaped hull, with fine lines, and is divided into three apartments, the forward one, or magazine, being filled with an explosive compound, which is fired by electricity. The middle compartment contains a roll of fine t[illegible]graphic wire about 1½ miles long whi[illegible] played out through an aperture in t[illegible] while in the after section is located the propelling engine, which drives a screw propeller at a velocity of, so far as tested, 12 miles an hour. The motive power is electricity, conveyed to the torpedo through the roll of wire referred to; and through this wire connection control is exercised over the screw and rudder, as well as the firing of the magazine. From the torpedo rises two stanchions, placed on each outer section, which connect with a light float, V-shaped on the sides and convex on the top. The torpedo proper is raised or lowered by means of the stanchions and float, so t[illegible] class of vessel with an overhang or partly armored can be reached by the impinging end of the torpedo, and the explosive power exerted at any depth of water desired. [illegible] seen in the water, nothing is seen but the c[illegible]t of the float with the heads of the stanchions, on which are placed tiny flags, which serve to show [illegible] ator the direction a[illegible] speed of the torpedo machine, and enable hi[illegible] and fire the charge of [illegible] pound. Thus far the [illegible] very successful. The el[illegible]attery for working this torpedo from f[illegible] kept within the fort or placed in a lamp-[illegible] near the scene of operations. It can also be operated from the deck of a cruising vessel or launch.

The annual amount paid for gas consumed by the public lamps of the City is about £14,000. The amount agreed upon for the electric lighting, by way of experiment, of three districts for 12 months, from sunset to sunrise, is £8,000. It is roughly estimated that the cost of the experiment, including the plant, machinery, fixing, replacing, and so on, will be about four times the price now paid for gas; but eliminating these expenses, which would not be recurrent, the cost would only be twice that of gas.

Tensile Strain and Electric Resistance.

Some interesting results showing the connexion between the electric resistance of iron wires and their state of strain have been communicated by Mr. W. H. Johnson, B. Sc., to the Manchester Literary and Philosophical Society. The wires were tested for their resistance by means of a Wheatstone balance with reflecting galvanometer of low resistance, and for their tensile stress by an apparatus similar in principle to a steelyard weighing machine. A series of measurements were made upon different varieties of iron wire, beginning with pure iron smelted and worked throughout with charcoal, and ending with highly carbonised steel wire. The results show that charcoal iron has the least electrical resistance, or about one-half that of piano steel; and it is noticeable that the resistance regularly increases as the impurities augment. Annealed steel, which comes about midway between pure charcoal iron and piano wire in the amount of carbon it contains, is also intermediate in point of electrical resistance. Annealing considerably diminishes the electrical resistance of puddled iron wire. The breaking strain and the resistance are also found to increase together [illegible]y regular manner. Annealing is found to dimi[illegible] the resistance of bright steel wire about 1 per cent., while hardening and tempering increase the resistance of annealed steel about 5 per cent. In fact any process, such as wire-drawing and tempering, which makes the particles of steel more rigid, would appear to increase the resistance of the metal to the passage of the electric current. With regard to torsion, the tests show that the electrical resistance is, roughly speaking, inversely proportional to the number of twists in the length of 8 in. The importance of electric conductivity in boiler plates is pointed out by Mr. Johnson in his paper. The heat conductivity of metals is nearly proportionate to their electric conductivity, and, as boiler plates should conduct heat well, they ought also to have a high electric conductivity.

Le Globe de Nantes

Machine électrique à composer.

40 Le Globe de Nantes

A la dernière exposition des imprimeurs, installée à Islington, près de Londres, se faisait remarquer une nouvelle ma[illegible] permettant d'assembler électriquement [illegible] caractères d'imprimerie, et dans laquelle le travail du compositeur se trouve réduit à sa plus simple expression.

Il suffit, en effet, d'un simple contact pour rendre libres les caractères rangés d'avance dans les casiers, lesquels caractères viennent se rendre d'eux-mêmes, automatiquement, là où ils doivent être assemblés, et le journal anglais l'*Electrician* nous assure, par l'intermédiaire de son collègue français, la *Lumière électrique*, qu'ils sont mis en place avec une rapidité et une précision qui n'avaient pas encore été atteintes.

Après un mois d'exercice, un compositeur ordinaire peut arriver facilement, avec cette machine, à assembler jusqu'à *douze mille* caractères en une heure.

Ce chiffre qui, au premier abord, peut paraître un peu phénoménal, a, nous assure l'*Electrician*, été constaté chez MM. Clowes, imprimeurs à Londres, où plusieurs exemplaires de cette machine sont employés actuellement. Il représente un maximum qui peut bien, en effet, être fourni pendant une heure, mais non, si agile et si infatigable que soit le compositeur, pendant plusieurs heures consécutives.

Lorsque les caractères quittent la machine, ils se disposent sur une ligne continue ; cette ligne est divisée à la main d'après la justification adoptée, pour former ensuite les colonnes et les pages.

En tenant compte du temps employé à la justification et à la mise en pages, on a calculé qu'avec l'aide d'un apprenti, employé pour charger de caractères les casiers, chaque machine pouvait fournir par heure la *composition* définitive et complète de *dix mille* caractères, et que la mise en place ou *distribution* de ceux-ci dans les casiers ne revenait pas à un penny, ou dix centimes par mille.

— L'enlèvement des caractères hors de leurs casiers s'effectue au moyen d'électro-aimants (aimants animés par un courant électrique), placés derrière chaque casier et correspondant à des plaques métalliques disposées en manière de touches qui, lorsqu'on appuie dessus, déterminent des contacts électriques. Chacune de ces plaques porte l'indication du caractère au[illegible]quel elle se rapporte.

Le compositeur est placé devant ces plaques comme devant un pupitre et procède comme il a l'habitude de le faire ; seulement, au lieu de prendre les caractères dans les casiers, il touche successivement les plaques qui leur correspondent avec une tige de cuivre qu'il tient dans sa main, comme il tiendrait une plume à écrire.

Par suite de ces contacts, les caractères quittent d'eux-mêmes, les uns a[illegible] les autres, leurs casiers respectifs pour se rendre à un collecteur où ils viennent s'assembler côte à côte dans l'ordre où l'on a opéré les contacts.

Au bout d'un certain temps de pratique, comme en télégraphie, le compositeur se trouve tellement familiarisé avec les positions relatives des diverses plaques de contact, qu'il n'a plus besoin de les chercher : sa main tombe sur elles d'une façon sûre et pour ainsi dire automati[illegible]

Les mouvements compliqués qu[illegible] ns le mode ordinaire de composition, la main du compositeur doit faire pour placer un caractère, étant réduits à un mouvement unique très simple, et les tâtonnements étant supprimés, il est facile de comprendre que par ce nouveau système, la composition d'un manuscrit puisse se faire, ainsi que l'attestent tous ceux qui ont assisté au fonctionnement, aussi vite que l'épellation même des mots.

Taille de la pierre à l'aide de l'électricité

Le *Moniteur des Inventions industrielles* nous fait connaître qu'une nouvelle application de l'électricité vient d'être faite en Amérique. Les journaux américains décrivent longuement une machine dynamo-électrique qui taille la pierre avec une grande perfection. Cette machine sort à dresser les meules et autres pierres, ainsi qu'à tarer les rocs, le tout avec précision et une notable économie.

Le ciseau employé à la taille est fixé à un ressort attaché lui-même à un coffre renfermant les aimants et les armatures. Le ressort, au moment où les aimants sont mis en contact avec la machine dynamo-électrique, reçoit de haut en bas un rapide mouvement qui, à chaque descente, fait agir le ciseau sur la pierre. On peut arriver à donner de 1,000 à 2,000 coups par minute.

L'emploi de fils conducteurs au lieu de tuyaux, comme dans les machines à vapeur, permet de déplacer la machine à volonté, de l'établir même à une certaine distance du chantier, sans trop grande déperdition de force, surtout si l'isolement des fils est complet, ce qui est facile à obtenir.

...n des avantages remarquables de cette invention réside dans le bâti portant l'appareil électrique. Ce bâti, étant mobile, peut se fixer où il est nécessaire. Il permet également de régler le mouvement circulaire du ciseau et de le rendre plus ou moins rapide, selon la nature plus ou moins résistante de la pierre ou de roc.

Au moyen de cette machine, on dresse très-rapidement une meule et l'on y trace les rainures voulues, avec cette régularité et ce parallélisme qui sont les qualités distinctives d'une bonne taille.

L'appareil peut marcher soit automatiquement, soit à la main; il est donc applicable à tous les genres de taille, à toutes les natures de pierre, tendre ou dure indistinctement.

Journal ... Annual ... 1881

An Electrical Reporting Machine.

A news despatch from Paris [of February 21st states that several successful experiments were made on the previous day at the Palais Bourbon with an electric reporting machine, which it is proposed to introduce into the Chambers. The machine has the appearance of a small piano, and is played like that instrument by an operator on a keyboard of ten notes. Three notes are set apart for reporting foreign quotations. As fast as the orator speaks the operator touches the keyboard, on which each sound has a corresponding key. The machine instantly represents the sounds by conventional signs on a strip of paper. The signs above afterward to be translated. About two years are required for learning how to manipulate and make use of the instrument, which is the invention of an Italian named Michela.

ENGINE[ERING] ...

[THE AUDIPHONE] AND THE TELEPHONE.

...n ... of deafness the auditory nerve itself ... it there is a proportion of instances in which ... apparatus of the ear is at fault. For deaf[ness] which belong to the latter category the Au[diphone] ... audiphone is very beneficial since it will enable them to hear music and conversation with very little trouble or expense. All these instruments consist of an artificial diaphragm of some elastic material, capable of vibrating under the impact of the sound waves and of communicating their vibration to the bones of the head and thence to the auditory nerve, when held between the teeth. Mr. Rhodes employed a thin disc of ebonite bent by a cord into a curved form and held before the mouth with the convex side outwards and the edge resting between the ... Professor Colladon substituted Bristol board for ebonite, and Mr. Fletcher, of Warrington, used birch wood veneer in place of Bristol board. The latter gentleman now, however, gets excellent results with a simple sheet of stiff brown paper having its edge placed loosely against the teeth, and its curved increased surface outwards. The audiphonic principle has also been applied quite recently to the speaking telephone by Mr. H. G. Fiske, of Springfield, Massachusetts, in order that persons habitually deaf from mechanical (not nervous) causes may be able to employ that useful apparatus. To the centre of the vibrating plate of the telephone is affixed a short rod of wood, ebonite, or hard elastic substance which can be held between the teeth, and allowed to vibrate there so freely that the vibrations of the telephone diaphragm can communicate themselves to the auditory nerve.

Awards to Workmen for Inventions.

Messrs. William Denny and Brothers, the well-known shipbuilders, Dumbarton, have notified their intention to establish a system of awards to workmen under the supervision of an Award Committee, under the following general conditions: "1. Any workman in our employ may claim an award from the Committee on the following grounds: (*a*). That he has either invented or introduced a new machine or hand-tool into the yard. (*b*). That he has improved any existing machine or hand-tool. (*c*). That he has applied any existing machine or hand-tool to a new class of work. (*d*). That he has discovered or introduced any new method of carrying on or arranging work. (*e*). Or, generally, that he has made any change by which the work of the yard is rendered either superior in quality or more economical in cost." There are in all eleven rules, any or all of which may be modified, changed, or annulled. The third rule is as follows: "On the establishment of a claim under the conditions above specified [in Rules 1 and 2] the Committee are to make an award, which is not to fall below 2*l*., nor to exceed 10*l*. Between these limits the award will be fixed by the Committee according to the opinion they may form of the value of the improvement or invention for which claim has been made." This arrangement is open to the obvious criticism that the maximum award is entirely inadequate for anything but minor improvements or advantageous modifications, which, we presume, it is only intended to deal with.

Weather Information.

It may not be generally known that descriptions of the actual state of the weather, and forecasts for not more than one day in advance, are prepared at the Meteorological Office for issue to the public. They are posted at the door of the office, 116, Victoria-street, S.W., on week days, for the inspection of the public. Any person can be supplied with ... once on each week day, on ... of ten shillings per an[num] ... of transmission either by ... any person applying at the off[ice] ... on week days, and be ... Sundays, can be supplied in ... with the latest information in of the office, and with the latest forecast is a specified district, on payment of one for each inquiry. Application may be by letter, enclosing thirteen pence in st[amps] if the reply is to be by post, and two shillings ... the reply (not exceeding twenty words) is to be by telegraph. Any person may obtain by telegraph the latest information as to the weather in any district of the United Kingdom by payment of a fee of one shilling in addition to two shillings, the cost of the message and the reply. The telegram containing the inquiry must not contain more than twenty words. Application may also be made for simi[lar] information to be sent either by telegraph [or] post on some future specified day.

On the Comparison of Declination Magnetographs at var[ious] Places, by Prof. W. G. Adams.—This paper was accompan[ied] by diagrams of simultaneous magnetic disturbances at St. Petersburg, Kew, and Vienna, showing that many of the sudd[en] magnetic disturbances occur simultaneously over very great are[as], but that in some cases the variations were in opposite directio[ns]. In the debate which followed Sir Wm. Thomson spoke of th[ese] observations as beginning to open out a glimpse of the true cau[se] of the magnetic storms. He observed that if similar records [of] the other magnetic elements, inclination and intensity, could [be] procured, we should know definitely whether these disturbances were due to any changes of the magnetism of the earth itself, or whether they were due to an external magnetic action. Magnetic observations had been going on for forty years, and it was a reproach that more had not hitherto been done. He also referred to the alleged connection between auroræ and magnetic storms. Mr. J. Glaisher and Staff-Commander Creak men[tion]ed cases of sudden magnetic disturbances. Capt. Creak re[ca]lled the observations of the Arctic expeditions of 1875-6, when a deflection of 5° was observed within forty minutes, the Kew records showing synchronously a smaller fluctuation. He argued that an observing station in a more northerly latitude was necessary. Mr. W. H. Preece recounted a magnetic and electrical storm which affected Ireland and the west of England on Aug. 12. Magnetic disturbances always were accompanied by earth currents which affect the telegraph-wires. The same storm affected even the Atlantic cables and the Cape cable. He believed they would be found to have affected the whole earth. The electromotive force on this occasion, through the Atlantic cable, was about as great as that of 300 Daniell's cell, or more exactly one volt per 6·6 miles. Capt. Creak also exhibited the new Admiralty charts of the magnetic variation for 1880.

Nature Sept 1880

Prof. G. H. Minchin read a communication *On Photoelectricity*. He had obtained feeble currents from two silver plates coated with sensitive films of iodide, chloride, or bromide of silver, dipping into a common fluid, and then one of them exposed to the light. He had also observed that preparations of fluorescent and phosphorescent bodies upon silver plates acted similarly.

Prof. Silvanus P. Thompson gave a paper *On Electric Convection Currents*, pointing out their analogies with true conduction currents, and of currents of electrolytic conductivity in respect of electro-magnetic phenomena. The application to ...ing-figures produced by disruptive convection and by electrolytic conduction was considered, and their deformation in the magnetic field. It was pointed out that considerations of a similar nature had been advanced by Prof. Ayrton at an earlier date.

[Exp]eriments on Thin Films of Water, with regard to the [Abso]rption of Radiant Heat, by the Hon. F. A. R. Russell.—The experiments, the general results of which are given below, were made with the object of ascertaining the diathermancy of water in very thin films, and these experiments afforded incidentally an opportunity of observing the behaviour of films subject to varying conditions.

The arrangement of instruments was similar to that illustrated at p. 383 of Prof. Tyndall's "Heat as a Mode of Motion." The instruments used were a dead-beat mirror galvanometer and scale, a thermopile, and a screen. The soap film was carried by a piece of cork sole perforated by a hole slightly larger than the hole in the screen, about 1¼ inch in diameter. The sources of heat were (1) a copper or iron ball heated from behind by a small gas flame; (2) a gas flame from a Bunsen burner and (3) [h]ydrogen flame in air.

[Th]e film was mostly made from a solution of about half a ... of shavings of Castile soap, dissolved five to fifteen [i]n about five cubic inches of water, at 60° F.

[The f]ilm, soon after being placed perpendicularly at the orifice [of the] screen, exhibited coloured bands, which descended in [regul]ar succession until the last band appeared, which contained [a bri]ght blue line. The descent of the bands continued at a [slack]ened rate till the grey, and finally the black, occupied a po[rti]on of the upper half of the film, which half was alone su[bj]ect to experiment. A condition more or less of equilibrium then prevailed, the tension of the black portion counteracting the forc[e] of gravity. A light yellow or bronze was always the last colour to appear, and preceded the white or grey, which again was succeeded by black. When there was any black in the film, the bursting of the film was marked by a slight click or [po]pping sound. The best films lasted frequently between ten [and] thirty minutes, and sometimes the black portion alone was [un]der observation fifteen or twenty minutes.

The following table shows the absorption per cent. for each of the three sources of heat, and the thickness of the film, as derived from a table in Watt's "Dictionary of Chemistry," giving Newton's thicknesses of thin films of air, water, and glass. A [ta]ble in Cooke's "New Chemistry" gives the thicknesses of ...-films as considerably greater than those stated in Newton's ... The "light film" of Cooke corresponds to my "grey," ... "grey" to my "fine grey." Newton's "white" corre[sponds] to my "grey." The refractive index of the solution [found b]y me was 1·34 and 1·35, a little higher than that of pure [wat]er.

State of Film.	Metal.	Gas.	Hydrogen.	Thickness of Film in millionths of an inch.

SECTION ... SCIENCE

On the Influence of Water on the Union of Carb[onic Oxide] with Oxygen at a High Temperature, by Harold B. [Dixon].—The author c... the curious re[sult] th[at a mixture of carb]onic oxide and oxygen in such proportions as to form carbon dioxide, when [fr]ee, or nearly free, from water, does not explode, either by a direct discharge from a Leyden jar or when sparks are passed through it from a Ruhmkorff coil. By allowing a minute portion of aqueous vapour to mix with the gases, explosion immediately takes place on the passage of the spark. In presence of a very small trace of water, combustion takes place, but slowly, not with explosive energy. The author suggests as an explanation the following equations:—

$$CO + H_2O = CO_2 + H_2$$
$$H_2 + O = H_2O.$$

Prof. Williamson suggested that it would be interesting to determine the inferior limit to the power of water vapour in causing an explosion, and that Mr. Dixon would probably extend his research in this direction.

Prof. Harcourt pointed out that various other similar instances are known, among others the impossibility of causing union of calcium oxide and carbonic anhydride, in absence of water, and the refusal of dry chlorine to act on hot sodium.

Mr. Thomas noticed that in mixtures containing large amounts of marsh-gas the presence of water vapour also influenced the rapidity of explosion.

26 Eng. Mech & World Science May 25 1881

... ung-iron, ...ted by the electric current, and capable of ...ll kinds of solders, such as gold and silver solder (which have hitherto required n blowpipe), has been patented in America by Mr. Ball, of Philadelphia. The electrodes extend through and project beyond the handle, and embrace a piece of platinum or other material offering sufficient resistance to the current to get heated more or less. One of the conductors is interrupted near one end of the handle, and bridged by a button, made partly of conducting and partly of insulating material, so that by turning the button, the circuit may be completed or broken as desired. In another arrangement, the handle is in two halves, pressed apart by a spring, and, in that position, short-circuiting the current. On pressing the halves together the current is sent through the refractory point.

...RO E...IC MINE EXPLODERS.

...SIEMENS' APPARATUS.

40

(*Continued from page 275.*)

The small quantity-exploder is of the same construction as the large one, but its weight, including knapsack, is only 39 lbs. It fuses a quarter of an inch of 0·0015 inch iridio-platinum wire through a line resistance of 50 Siemens' units. With short leading-wires this exploder beats 8¾ inches of iridio-platinum wire of 0·0015 inch diameter, which is equal to about 35 Service Detonators, No. 13. Dimensions of the exploder, 12" × 11" × 6".

With a given electro-motive force the quantity of current passing through a circuit per unit of time depends upon the resistance of the circuit; hence, if only one quantity-fuse be connected up with the exploder, a stronger current will be generated than when several fuses are joined in series. Thus, with a small exterior resistance, a large quantity of current passes from the armature into the electro-magnets of the machine, whereby a ... powerful magnetic field is formed and the revolving armature experiences a resistance to its motion, which may become so great as to render the turning of the handle of the machine difficult. In order to overcome this inconvenience ... much as possible, an extra coil of several units resistance is inserted in the base of the instrument. This extra coil may be increased in resistance 10 or 20 units if the machine be required to turn with greater ease. When the firing-key is at rest, the extra coil is in circuit with the electro-magnet coils, but when the key is depressed the extra coil is cut out, and the line and fuses put in circuit.

The only reliable test of the efficiency of tension-exploders is length of spark, as, owing to the great difference in the resistance of tension-fuses, any standard of efficiency based upon the number of such fuses an exploder will fire must be incorrect. The test for the quantity-exploder is the length of iridio-platinum wire of a standard diameter which can be fused.

The nature of electricity of great electro-motive force, by which it overcomes high resistances, requires that the coating of the cable or conducting wire should have high resistance, or, in other words, be well insulated, in order to prevent escape of the electric current. It should be borne in mind that to "insulate a wire" means to surround the wire with a covering which offers sufficient resistance to the escape of the electric current, and, consequently, that the greater the electro-motive force the greater is the resistance required in the insulating covering.

In cases where the conducting wires are for the greater part of their length stationary, high tension electricity is to be preferred, because its greater power of overcoming resistance enables it to fire a larger number of fuses through longer distances. On this account the tension-exploder is better suited to mining purposes, where fuses have to be exploded either in numbers *simultaneously* or through *long* circuits.

But in cases where only short lengths of conducting wires are employed, and these are frequently shifted or subjected to such rough usage as would endanger the insulation of the cable, the use of electricity of *small* electro-motive force is advisable, for this will pass without loss through a cable with faults in the insulation through which currents of greater force would readily escape. On this account the quantity-exploder should be employed.

The mistake of using weak machines has done much to hinder the adoption of electrical firing.

The dynamo-exploders are unquestionably the most suitable for blasting, and of the two kinds of apparatus the tension-exploder is usually preferred in consequence of tension-fuses being cheaper than platinum wire-fuses. When, however, a system of mines has to remain a long time inoperative, and yet in a condition to be fired at a moment's notice, daily electrical tests must be taken, and this can only be done when platinum wire-fuses are used.

There are two kinds of fuses adapted to the two kinds of electric-exploders, viz.:—

(*a*) Tension fuses.
(*b*) Quantity fuses.

Tension-fuses should be made of stable elements, so that no chemical decomposition can take place in the priming, and the fuses must remain unaffected by moisture and heat, even when used in tropical climates. The composition of tension-fuses should likewise keep unchanged during a long sea voyage, as many failures in electric blasting abroad have been due to a chemical change in the fuses or to the mass of the priming having become loosened during transport. It is important, in connecting up the fuses in circuit for firing, that great care should be taken not to put too much strain upon the fuse wires, otherwise these wires are apt to be pulled out of the explosive compound, and the fuse cannot then explode. The data given below respecting the number of fuses fired by Siemens' exploders refer to Abel's fuses only.

When a number of fuses are joined in single circuit the resistance of each fuse is added to that of the entire circuit, but when connected in divided circuit the joint resistance of the fuses is less than that of a single one only. In cases where an unusually large number of *tension-fuses* are required, the *divided circuit* may be used, but the connections are *troublesome* to make, and as a sufficient number of fuses can be fired in *single* circuit, this latter

Eng. Mech

THE SILK INDUSTRY OF THE UNITED STATES.—ITS G... T FUTURE.

THE following very able report by Consul Peixoto, of ...ons, will be read with interest not only by our silk manufacturers, bu... every man who has the building up of our industries at heart:

The United States is no less interested in this serious question. We are now annually producing upwards of $30,000,000 worth of silk fabrics, and yet not one single silk filature worthy of the name exists in all our broad dominions. Besides we are wholly dependent upon Europe and Asia for our raw material.

Two questions present themselves at this juncture: the first is, can we raise silk? The second, can we sell it when we have raised it? The first has already been solved; we can raise silk worms because we can grow the mulberry leaf which is its essential food. This question has been conclusively determined. Silk worms have been successfully raised in the United States for more than thirty years. The second remains. The impossibility hitherto of competing with the cheap labor of Europe, where the silk reeler receives but thirty cents a day, and of China and Japan, where but from six to ten cents is paid, has been the principal, in fact the only, cause why we have not and could not sell the silk from the cocoon. Every silk manufacturer will admit the desirability, nay for permanent success, the absolute necessity of having his raw material at hand, even as the cotton manufacturer has his.

To be absolved from the necessity of importing from Europe and Asia the raw material, would be next to constituting the silk industry with us as one of the great sources of our national wealth. It would give employment to hundreds of thousands of hands, women and children, now idle or non-producing; it would at the same time afford the masses an elegant and durable mate...al at one-third less than the present cost, and it would give to capital a new and lucrative source of investment shared at present but by a few individuals, and restricted to exceedingly limited proportions.

But how can we overcome the competition of Europe and Asia with regard to labor? I am happy to be able to answer this question here and now. In the month of June last, recommended by the Department of State, which under the present administration has done so much to encourage our home manufactures and develop our foreign trade, and provided with letters by the commissioner of agriculture, there came to Europe a young American engineer who, before leaving home had already given much time and study to the subject, and who since has devoted several months to visiting and carefully inspecting the principal filatures of France and Italy. This gentleman, Mr. Edward W. Serrell, Jr., of New York, believed it possible to invent machinery which, by the use and application electricity, would not only overcome existing difficulties, produce a superior quality of thread, but solve at the same time the all important labor question and render silk reeling in the United States as possible and profitable as anywhere else in the world.

It affords me very great satisfaction to say that in my judgment Mr. Serrell h... at length been successful, and that very shortly this fact will be abundantly and incontestably proven, both for the now unhappy and rapidly declining silk reeling industry of Europe as well as for, from one American point of view still more important and valuable interest, the successful planting of silk industry in the United States in all its varied stages and branches from the mulberry tree, the *magnanerie* or hatching house, the reeling mill to a still higher perfection than what we have already attained in the fabrication of tissues. What the cotton gin has done for cotton, which with us ninety years ago hardly had a commercial value, the Serrell invention may yet do for silk, and the United States become pre-eminent for the latter and costlier product as for the former and cheap... culture.

The capital point to be derived from these exhibits is the decline of French filatures, and to note that this decline was produced from (1.) inferior crops (2.) decreased consumption of pure silk goods; (3.) superiority of Italian filatures (4.) competition of China and Japan labor; and to add that this deplorable st... could easily be revived and resuscitated by the introduction of improved a... economical machinery.

played upon. Upon depressing any given key, the movable pin working in connection with this key is also depressed and marks a ... line on the paper, the length of the line corresponding to the time the note is held down. The pins are also so placed, that if a ... fall inconveniently high or low, the note ... an octave lower or higher, as the case may be, ... the proper octave indicated by a mark produced in a similar manner.

Eng Mech Jan 7 1881

Dr. Siemens's electric lift, which has been exhibited at the Mannheim Industrial Exhibition, is a useful invention. The cage is carried by wire ropes, having counter weights, so that the cage, when loaded, is practically in equilibrium. The current-generator at the base is electrically connected to the dynamo-machine in the cage, and the latter actuates two toothed wheels taking into a metal rack running up the centre of the passage-way of the lift.

Eng Mech & Wld Science
March 18. 1881

An apparatus for determining the velocity of a projectile in cannons and rifles, is described in the *Revue d'Artillerie*. It is the invention of MM. Siemens and Halske, and seems in the main a development of previous methods. The projectile passing along the bore brings the bare ends of several insulated wires into contact with the gun, and on each contact, a platinum wire opposite a rotating blackened drum, delivers a spark, marking the surface. This is effected through the agency of an induction apparatus, and a battery of 8 Leyden jars, the former being connected with the outer surface of the jars, and the interior of each of the latter with a gun wire. The highest knob of the battery is connected with the platinum wire which gives the sparks. As the projectile makes contact, the positive electricity of the wires flows to earth, and the spark passes.

40

Two ingenious pieces of electrical apparatus for lighting and extinguishing lamps have recently appeared. In one of them (M. Margret's system) the oil-lamp stands on a base in which is a horizontal electro-magnet. From the armature of this rise two parallel curved rods of copper, joined at the top by a platinum spiral, which is rendered incandescent by a battery current, and brought in that state to the wick, when the armature is attracted. In this movement towards the wick, a small bellows is compressed, giving a puff of air through a tube rebounding on the wick. In the case of lighting the lamp, this puff has no effect, but when the lamp has been burning, and is to be extinguished, the puff produced by a momentary passage of the current blows the flame out, and there is not time for the spiral to relight the lamp. In the other system (that of M. Ranque), a platinum spiral is brought to the wick, much in the same way, but the lamp is put out by an extinguisher at the end of a curved and pivoted wire. The contrivance is such that the extinguisher is brought down to the wick, or raised from it (through attraction of the armature) according as the flame is to be put out or lit. (Both lamps are figured in *La Nature*, No. 401.)

Ironmonger. Apr. 16. 1881.

Electric Apparatus.—There is a pretty good demand for electric apparatus, and the question of electric lighting appears to be disturbing the municipal mind both in Manchester and Salford. Although nothing very definite seems yet to have been done in the matter by either body, the conversation I have had with members indicates that they are looking upon the progress of the electric light as making it a very probable competitor with gas for street-lighting. Amongst other descriptions of electric apparatus, I may record that Messrs. W. H. Bailey, of Manchester, are manufacturing for the lunatic asylums an apparatus for recording the punctuality of the visits of the night nurses and watchmen through the various wards. These have lately been fixed at Hereford and Chester asylums, and orders have recently been received from other establishments.

et des ouvertures ne dépassant pas trois quarts de millimètre de diamètre.

Cette lampe présente cette propriété remarquable que, malgré la température élevée de la combustion, elle s'échauffe peu, consume très-peu de pétrole, et ne charbonne presque pas, si bien qu'elle fonctionne pendant plusieurs journées sans qu'on ait besoin de toucher à la mèche et de renouveler le liquide.

Cela tient à ce que la mèche ne dépasse pas le cylindre qui la contient, que la flamme intense est produite par la combustion de la vapeur du pétrole et au centre du bec, de telle sorte qu'elle est séparée de lui par une couche gazeuse mauvaise conductrice. Il en résulte que même après plusieurs heures de fonctionnement continu, il n'y a de chaud dans la lampe que la partie supérieure du bec.

Le seul inconvénient de la lampe est qu'il se produit de temps à autre, dans l'ouverture donnant accès à l'oxygène, un léger dépôt de matières étrangères carbonisées sous forme d'une sorte de petit cône incandescent; mais on le fait disparaître sans difficulté en soufflant dessus ou à l'aide d'une petite tige, sans éteindre la flamme.

En revanche, la lampe présente, au point de vue spécial qui nous occupe, une propriété particulièrement favorable. Lorsqu'on l'allume sans oxygène, elle donne une flamme fuligineuse qui n'éclaire pas; mais, quand on fait arriver le gaz, elle prend une intensité rapidement croissante et elle atteint son maximum dans un temps très-court; si bien que si l'on met la flamme intense au foyer d'une lentille, de façon à produire un faisceau lumineux parallèle sur un écran éloigné, ce faisceau est très-éclairant, tandis qu'il est à peu près obscur avec la flamme non alimentée de gaz.

Il en résulte la possibilité de faire varier rapidement son intensité d'une quantité considérable et, par suite, de l'utiliser économiquement pour faire des signaux lumineux intermittents.

Il suffit, en effet, pour arriver à ce résultat, de faire dégager l'oxygène brusquement au centre de la flamme et de le supprimer brusquement; on peut y parvenir de plusieurs manières. Celle à laquelle je me suis arrêté est la suivante : l'oxygène, enfermé dans un réservoir sous pression convenable, arrive d'abord à un manipulateur dont la forme est celle d'une clef d'appareil Morse, à travers un tube en caoutchouc, qui, à l'état de repos de la clef, est pressé dans une sorte de guillotine; puis le tube se continue jusqu'à la lampe.

Lorsqu'on abaisse la clef, la pression sur le tube cesse, et l'oxygène se rend dans la flamme; quand la clef se relève, le jet d'oxygène cesse, de telle sorte qu'on *manipule* en quelque sorte l'oxygène, à l'aide d'une manœuvre aussi simple que celle qui constitue la manipulation d'un courant électrique dans le système de Morse.

La rapidité de cette manipulation est plus que suffisante pour les besoins de la télégraphie optique, eu égard au phénomène de la persistance des impressions lumineuses sur la rétine, qui exige une certaine lenteur dans la production des signaux afin d'éviter leur confusion.

Ce système a été adapté à des appareils de télégraphie optique et il donne de bons résultats même dans la télégraphie militaire en campagne. A cet effet, l'oxygène est transporté dans des réservoirs en cuivre dont le poids n'excède pas 8 kilogrammes, et qui en contiennent environ 200 litres à la pression de 20 atmosphères. Dans les conditions habituelles, il y en a assez pour plusieurs jours de travail. Rien n'est plus simple d'ailleurs que de préparer de l'oxygène, de le refouler dans les réservoirs, et de transporter ceux-ci qui constituent un matériel peu encombrant.

Il est à remarquer que cette lampe n'a pas besoin de tirage; elle est donc sans cheminée. Il est vrai qu'il en résulte qu'elle fume quand l'oxygène n'y arrive pas, mais en plein air cela n'a pas d'inconvénient, et dans une station fixe il est toujours facile de se débarrasser de la fumée. Du reste, on peut y adapter, si l'on veut, une cheminée en tôle avec des ouvertures bouchées par des lames de mica.

Quoi qu'il en soit, on voit que nous avons là une solution économique de la question de la production de signaux intermittents à l'aide d'une source lumineuse intense particulière.

Ces solutions peuvent être d'ailleurs rangées en deux catégories générales : 1° celles dans lesquelles on agit, pour produire l'intermittence, sur l'agent même de la combustion d'où résulte la source lumineuse, 2° celles où l'on agit sur l'agent combustible.

Dans celle qui vient d'être exposée, on agit sur l'agent de la combustion qui est l'oxygène, en rendant intermittent l'écoulement du gaz. Mais on pourrait aussi, si on ne voulait pas économiser l'oxygène, agir sur le combustible, en abaissant et soulevant alternativement la mèche imbibée de pétrole à l'aide d'un pignon à crémaillère, mis en mouvement à l'aide d'une clef Morse. Et, par exemple, on obtient facilement de bons résultats en ce genre en agissant sur une lampe ordinaire à pétrole, à mèche plate, alimentée à la manière ordinaire par un courant d'air, car au-dessous d'un certain niveau, la mèche ne produit qu'une combustion insignifiante, et sa flamme n'est d'ailleurs pas visible extérieurement, enfermée qu'elle est dans le petit dôme fendu en laiton qui existe dans toutes les lampes de ce genre, tandis que si la mèche dépasse tant soit peu ce dôme, la flamme prend immédiatement tout son éclat.

Cette étude avait été écrite (au point de vue particulier de ce Journal) en vue d'un mode d'utilisation économique de la *lumière électrique*.

Effectivement, on conçoit qu'on puisse appliquer les principes précédents à cette lumière, et obtenir deux solutions générales du problème résolu pour la lumière du pétrole oxygéné. Car on peut produire une lumière électrique intermittente; soit en agissant sur le combustible, les charbons, par exemple, entre lesquels se produit l'arc électrique, produisant, maintenant et brisant cet arc à l'aide de mécanismes convenables; soit en fermant, maintenant et rompant le circuit électrique de la pile ou de la machine qui produit le courant.

J'ai pu, en effet, réaliser ces deux solutions, et principalement la première, et c'est celle que je me proposais d'exposer ici, en décrivant les appareils que j'emploie à cet effet; mais,

40

DR. SIEMENS' ELECTRICAL FURNACE.

At a meeting of the Society of Telegraphic Engineers, Dr. Siemens gave the following description of his electrical furnace:

Amongst the means at our disposal for effecting the fusion of highly refractory metals, and other substances, none has been more fully recognized than the oxy-hydrogen blast. The ingenious modification of the same by M. H. Ste.-Claire Deville, known as the Deville furnace, has been developed and applied for the fusion of platinum in considerable quantities by Mr. George Matthey, F. R. S.

The Regenerative Gas Furnace furnishes, however, another means of attaining extremely high degrees of heat, and this furnace is now largely used in the arts—among other purposes, for the production of mild steel. By the application of the open hearth process, 10 to 15 tons of malleable iron, containing only traces of carbon or other substances alloyed with it, may be seen in a perfectly fluid condition upon the open hearth of the furnace, at a temperature probably not inferior to the melting-point of platinum. It may be here remarked that the only building material capable of resisting such heats is a brick composed of 98.5 per cent. of silica, and only 1.5 per cent. of alumina, iron, and lime, to bind the silica together.

In the Deville furnace an extreme degree of heat is attained by the union of pure oxygen with a rich gaseous fuel under the influence of a blast, whereas in the Siemens furnace it is due to slow combustion of a poor gas, potentiated, so to speak, by a process of accumulation through heat stores or regenerators.

The temperature attainable in both furnaces is limited by the point of complete dissociation of carbonic acid and aqueous vapor, which, according to Ste.-Claire Deville and Bunsen, may be estimated at from 2500° to 2800° C. But long before this extreme point has been reached, combustion becomes so sluggish that the losses of heat by radiation balance the production by combustion, and thus prevent further increase of temperature.

It is to the electric arc, therefore, that we must look for the attainment of a temperature exceeding the point of dissociation of products of combustion, and indeed evidence is not wanting to prove the early application of the electric arc to produce effects due to extreme elevation of temperature. As early as the year 1807, Sir Humphrey Davy succeeded in decomposing potash by means of an electric current from a Wollaston battery of 400 elements; and in 1810 the same philosopher surprised the members of the Royal Institution by the brilliancy of the electric arc produced between carbon points through the same agency.

Magneto-electric and dynamo-electric currents enable us to produce the electric arc more readily and economically than was the case at the time of Sir Humphrey Davy, and this comparatively new method has been taken advantage of by Messrs. Huggins, Lockyer and other physicists, to advance astronomical and chemical research with the aid of spectrum analysis. Professor Dewar, quite recently, in experimenting with the dynamo-electric current, has shown that in his lime tube or crucible several of the metals assume the gaseous condition, as demonstrated by the reversal of the lines in his spectrum, thus proving that the temperature attained was not much inferior to that of the sun.

My present object is to show that the electric arc is not only capable of producing a very high temperature within a focus or extremely contracted space, but also such large effects, with comparatively moderate expenditure of energy, as will render it useful in the arts for fusing platinum, iridium, steel or iron, or for affecting such reactions or decompositions as require for their accomplishment an intense degree of heat, coupled with freedom from such disturbing influences as are inseparable from a furnace worked by the combustion of carbonaceous material.

The apparatus which I employ consists of an ordinary crucible of plumbago or other highly refractory material, placed in a metallic jacket or outer casing, the intervening space being filled up with pounded charcoal or other bad conductor of heat. A hole is pierced through the bottom of the crucible for the admission of a rod of iron, platinum or dense carbon, such as is used in electric illumination. The cover of the crucible is also pierced for the reception of the negative electrode, by preference a cylinder of compressed carbon of comparatively large dimensions. At one end of a beam supported at its centre is suspended the negative electrode by means of a strip of copper, or other good conductor of electricity, the other end of the beam being attached to a hollow cylinder of soft iron free to move vertically within a solenoid coil of wire, presenting a total resistance of about 50 units or ohms. By means of a sliding weight, the preponderance of the beam in the direction of the solenoid can be varied so as to balance the magnetic force with which the hollow iron cylinder is drawn into the coil. One end of the solenoid coil is connected with the positive, and the other with the negative pole of the electric arc, and, being a coil of high resistance, its attractive force on the iron cylinder is proportional to the electromotive force between the two electrodes, or, in other words, to the electrical resistance of the arc itself.

The resistance of the arc was determined and fixed at will within the limits of the source of power, by sliding the weight upon the beam. If the resistance of the arc should increase from any cause, the current passing through the solenoid would gain in strength, and the magnetic force, overcoming the counteracting weight would cause the negative electrode to descend deeper into the crucible; whereas, if the resistance of the arc should fall below the desired limit, the weight would drive back the iron cylinder within the coils, and the length of the arc would increase, until the balance between the forces engaged had been re-established.

The automatic adjustment of the arc is of great importance to the attainment of advantageous results in the process of electric fusion; without it the resistance of the arc would rapidly diminish with increase of temperature of the heated atmosphere within the crucible, and heat would be developed in the dynamo-electric machine to the prejudice of the electric furnace. The sudden sinking or change in electrical resistance of the material undergoing fusion would, on the other hand, cause sudden increase in the resistance of the arc, with a likelihood of its extinction, if such self-adjusting action did not take place.

Another important element of success in electric fusion consists in constituting the material to be fused the positive pole of the electric arc. It is well known that it is at the positive pole that the heat is principally developed, and fusion of the material constituting the positive pole takes place even before the crucible itself is heated up to the same degree. This principle of action is of course applicable only to the melting of metals and other electrical conductors, such as metallic oxides, which constitute the materials generally operated upon in metallurgical processes. In operating upon non-conductive earth or upon gases, it becomes necessary to provide a non-destructible positive pole, such as platinum or iridium, which may, however, undergo fusion, and form a little pool at the bottom of the crucible.

In this electrical furnace some time, of course, is occupied to bring the temperature of the crucible itself up to a considerable degree, but it is surprising how rapidly an accumulation of heat takes place. In working with

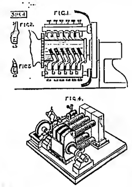
Nature, July 28th 1881.

Prof. Graham Bell has sought to prove whether the diaphragms subjected to intermittent radiation in one of the forms of the radiophone did or did not execute mechanical vibrations. The experiment of Mr. W. H. Preece of attaching a Hughes' microphone to the disk had led to negative results. But Prof. Bell has shown that the central region of the disk (on which the rays fell) is set into mechanical vibration; and he has proved the point by employing a modification of the mechanical microphone of Wheatstone. A stiff metallic wire is fixed to the centre of a thin metallic disk mounted at the extremity of a flexible hearing tube. When the end of the wire is pressed against any vibrating body its sounds are heard, and the vibrations at different points of the disk of a radiophone can be successively explored. The vibrations are found to be almost entirely confined to the illuminated area at the centre of the disk. A Hughes' microphone attached to the edges of the disk would therefore not easily give any indications. With this simple apparatus one very curious effect was obtained. An intermitted beam of rays was focussed upon a brass kilogramme weight, and the surface was explored with the point of the metallic microphone. Over all the illuminated area, and for a very short distance outside it a feeble but distinct sound was detected, but not over other parts.

The Electrician, June 11th 1881

3964. Improvements in Magneto or Dynamo-Electric Machines, P. Jensen.—Dated 30th September, 1880.—(A communication from T. A. Edison.) 10d.

The principal improvements described relate to (1) the commutator brushes. Each brush or spring is secured at an angle in a holder, so that the brush bears obliquely upon the commutator. The holder is pivotted on a U-shaped jaw. At the pivotted point of the holder is a chamber, in which is a spring, whose force is exerted to throw the brush upon the commutator. Figs. 1, 2, and 3 show the arrangement. (2) Describes how the prime motor is preferably connected directly to



the dynamo machine, and both mounted on one base as on Fig. 4. Another part of the invention describes the means of communicating motion from the rotating armature to the driven mechanism without the use of belts, gear or similar devices. Further, the coil is so made as to be removed or repaired without disturbance of the remainder. This is accomplished by making of wire only that portion of the coil which is upon the operative face, the wires of a coil being connected at the ends by metallic plates, fastened to an insulating base, and insulated from each other.

The Electrician, June 11th 1881

4005. Improvements in Dynamo-Electric or Magneto-Electric Machines, E. G. Brewer.—Dated 2nd October, 1880.—(A communication from A. J. B. Cones.) 6d.

This apparatus is essentially composed of one or several induction crowns or rings on a support

in the form of a wheel mounted on the shaft of the machine. The figure shows a double crown of these induction coils.

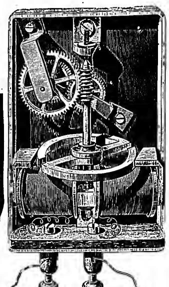
English Mechanic & World of Science August 19, 1881.

[41171.]—Electric Clocks.—Although unable to answer the first part of this query, I may tell "M.M.I.Se.S." that it is certainly not necessary for the controlled pendulum to swing the opposite way to the standard one. They may just as easily be made to swing in the same direction by properly arranging the currents and magnets; at the same time, it doesn't matter a pin which way they swing. As to the number of cells required, it evidently depends upon what cells are used, and the resistance of the circuit; but I think there are not many electric clocks capable of being driven for any length of time by one cell. I am at present engaged experimenting upon a system in which the controlled pendulum beats half-seconds, and only receives its impulse every second, or every two seconds with a more powerful battery. This bids fair to be successful. I have had one clock going a considerable time all right, and am now making another on the same principle, but simpler in construction, more independent of variations in battery power, more compact, and last, but not least, noiseless. If successful, will report to E.M. —J. E. Floyd.

21 36 Scientific Am. Nov. 5. 1881.

ELECTRIC CLOCK-DIAL MECHANISM.

The construction of a perfect electric clock involves several difficult problems, and it is this which explains in part the existence of a large number of electric clocks varying in



ELECTRIC CLOCK-DIAL MECHANISM.

efficiency according to the attention paid to the fundamental principles which should control their construction.

Electricity actually plays three very distinct characters in the electrical clock, and the Paris Electrical Exposition presents numerous examples of this:

1. Electricity is made use of as a motive power, to swing a pendulum and replace the springs or weights of an ordinary clock.

2. Electricity is employed for transmission. A central clock sends an electric current every second, half minute, or minute, to one or more dials placed at a distance, which causes the hands to advance respectively a second, a half minute, or a minute.

3. Electricity is employed to regulate clocks and dials propelled by ordinary weights and springs, and adjusts the hands every hour, every six hours, or every twenty-four hours. It is this system of synchronism which has been adopted by the city of Paris for the public clocks.

We do not wish to discuss here the respective advantages of the two systems of distribution of time in a city by electric transmission or by electric adjustment effected at fixed intervals. The electric distribution of time has some special advantages which are not possessed by the system of electrical adjustment, and the disadvantages disappear in proportion as the apparatus is perfected and simplified. The pneumatic clock established in Paris two years ago has a transmitter operated by compressed air.

The engraving represents a simple electrical dial mechanism which exactly fulfills the requirements, working surely each minute under the action of the current sent by the central distributing clock.

All of the earlier forms of electrical dial apparatus are operated by an oscillating armature, moved by an electro-magnet and retracted by an antagonistic spring, or two electro-magnets acting upon a polarized armature. The movement of the armature is transmitted to the gearing by the levers and pawls, which must be very perfectly adjusted, as they cease to act if there is a little play, wear, or oxidation. In order to give a slight movement to the armature it is necessary to lengthen the lever immoderately.

All of these inconveniences are avoided in the very simple apparatus of M. Thomas, the mechanism of which is represented in the engraving. It is composed of a horizontal electro-magnet, the poles carrying two armatures, between which is placed a polarized armature in the form of an S, fixed upon a vertical axis. This axis carries an endless screw, which operates the minute hand and gearing. The transmitting clock sends into the electro-magnet alternate positive and negative currents at every half minute. The current sent is such that it develops in the poles of the electro-magnet alternate positive and negative polarity, so that the polarized S-shaped armature is first attracted and then repelled, causing a half revolution of the S-shaped armature for every electrical impulse. The current should continue from two to three seconds, in order that the polarized armature may be maintained in position. The endless screw carries along the gearing and causes the hands to advance each time.

In consequence of its inertia the polarized S shaped armature tends to pass beyond its half revolution, and the speed acquired toward the end of the half revolution is checked by means of a spring against which a pin carried by the vertical spindle strikes at each half revolution.

This simple and ingenious apparatus requires no regulation. The rotation will be produced, whatever may be the distance from the extremities of the polarized armature to the electro magnet, and this distance may vary from one to two millimeters.

The power of the apparatus is determined by the dimensions of the S shaped polarized armature of the electro-magnet, and by the size and length of the wire which surrounds them.

By using a high tension current of electricity a large number of these electrical dial movements may be placed upon the same circuit and made to operate dials of two meters in diameter.

At the Exposition of Brussels, in 1880, where the electric dial mechanism of M. Thomas was in operation for the first time, he had in the same circuit a large dial of 1·80 meters in diameter and eighteen other smaller dials of 0·50 meter and 0·40 meter. They worked perfectly, excepting the five or six interruptions proceeding from the stopping of the transmitting clock caused by the moving of the platform on which the clock was placed.—*La Nature.*

The Iron Age Nov. 27, 1881

Electricity Displacing Watchmen.

Application has been made by Pittsburgh parties for a charter for a corporation whose projectors claim will control a system for the prevention and detection of burglaries and fires, which will not only throw all the private watchmen in the two cities out of employment, but make Pittsburgh and Allegheny an exceedingly unhealthy place for law breakers generally. The corporation is to be known as the Stern Electric Alarm Company. As set forth in its charter, its objects are the prevention and punishment of theft and willful injury to property. The inventor is W. A. Stern, who for many years was associated with Edison. The company was organized several months ago, and by the first of next month expects to be ready for business.

The manner in which the plans of burglars are to be frustrated is thus explained by Mr. Stern: "Control stations will be established in Pittsburgh, Allegheny and the East End, and at each of these a good force of careful and experienced officers will be located night and day. Banks, business houses and private residences will be connected with these stations by wire, and will be so completely protected that even persons who have a right to do so cannot enter without the central station being notified. The plan is very simple. Windows and doors will be supplied with simple electric appliances in such a manner that their presence cannot be detected. The instant an attempt is made to open a door or raise a window a gong in the central office will ring, and an annunciator similar to those used in hotels will indicate the number of the building entered. For bank vaults or other places requiring extra precautions the doors or panels will be lined with electric wires so fine that a coil weighing 1 pound is 3 miles long. These wires will be so close together that, even if their presence or location is known, entrance cannot be effected without breaking or disturbing one or more of the wires, and so sounding the gong in the central office. One or more men will answer each alarm. The stations may be so close to the subscribers that any one can be reached in three minutes. The intruders will not know that an alarm has been sent in, and very few can do much in three minutes."

The electric current is also to be utilized in the detection of fires. Ceilings and other portions of buildings will be studded with thermostats—brass instruments about the length and thickness of a man's finger. These are so susceptible to heat that a match held for a quarter of a second within 6 inches of a thermostat will cause it to ring a gong miles distant. The fire-alarms will be taken on a separate gong from that recording the visits of trespassers. The fire department will be immediately notified, and in addition trained men will be sent to the place.

The company expects to begin business with 200 subscribers. Joseph T. Speer is president and Heber McDowell general inspector. C. F. McKenna, R. P. Duff, D. H. Gilkinson and P. M. King are among the directors. These gentlemen all claim that the Stern system has been thoroughly tested, and that there is no doubt of its practicability. The cost of the apparatus, they say, will average less than is now paid for private watchmen.

37

Iron – Jan 27, 1882

THE TELERADIOPHONE.—M. Mercadier, the eminent French electrician, has ingeniously adapted the photophone of Professor Bell to telegraphy. In the photophone a ray of light is reflected by a mirror, so as to fall upon the sensitive surface of a "selenium cell" joined up in the circuit of a voltaic battery and a speaking telephone. When the light strikes the cell its electric resistance is diminished, and a wave or pulse of current flows through the telephone, causing it to sound. By eclipsing the ray of light a great many times per second, this sound can be exalted into a continuous hum, like that of a tuning fork, and by again occulting the intermittent ray for long and short intervals corresponding to the flashes of a signalling lantern, this hum or drone can be broken up into audible signals. Thus, if the Morse telegraphic code is used a short occultation, producing a short pause in the note of the telephone, will stand for a "dot" and a long occultation, producing a long pause, will stand for a "dash." This photo-electric telegraph is realised by M. Mercadier with the help of a gas flame forming the source of light, a mirror and lenses to direct its rays upon the selenium cell in circuit with a battery and the line wire. The beam is regularly eclipsed by means of a rapidly rotating disc, perforated with a circle of holes, and the telegraphic occultations of the intermittent beam are effected by means of a signalling key, which interposes a dead screen in the track of the light whenever the key is pressed. These apparatus form the transmitter, and the receiver at the other end of the line is of course the telephone, which is fitted with a resonator to reinforce the sound. There is no gain in such an arrangement over the ordinary telegraph now in use; but it has the merit of lending itself to multiple telegraphy. Thus, by multiplying the number of transmitters at one end of the line and the number of telephones at the other, several different messages can be sent along the same wire at once. In order to do this it is only necessary to rotate the eclipsing wheels at different speeds, so as to produce notes of different pitch in the receiving telephones, and to fix each resonator so as to enhance a particular note. Then, although the complex current flows through all the telephones in turn, each telephone will only render to the ear of the clerk the particular note for which he listens, and the makes and breaks of that note will be interpreted as the message. Not only can several messages be sent in one direction along the same wire together, but from opposite ends simultaneously without confusion, and M. Mercadier reckons that with 10 transmitters and 10 receivers at each end of a line he can send 200 despatches of 30 words each per hour, or 100 words per minute, in either direction. The effects of induction, so troublesome to speaking by telephone, are not experienced in this process owing to the employment of musical notes and resonators.

Engineering Aug 84

An Electric Head Light.—An electric head light has been fitted experimentally to one of the engines of the Chicago, Milwaukee, and St. Paul Railroad. This application of the electric light is the invention of Mr. Wooley, of Indianapolis. Some days since his agent sought permission of the superintendent of the Chicago division of the Chicago, Milwaukee, and St. Paul Railroad to place one of his lights, with its engine, on one of the company's locomotives. The apparatus, which consists of a small 1½ horse-power rotary engine, and a box about 2 ft. square by 8 in. in thickness, containing the dynamo, &c., was placed upon the engine, directly in front of the cab on the left-hand side. The focus had been so adjusted as to cast the light a little to the right of the centre of the track. The light was exceedingly brilliant, and its power was estimated to equal 2000 candles.

Engineering Oct. 5 84

Position of the Poles of Magnets.

Messrs. W. Hallock and F. Kohlrausch have made a number of experiments on ordinary long bar magnets in order to determine with exactitude the true position of the poles in the length of the bars. Fourteen magnets were used, some of various conditions of hardness, and in general they were in the form of steel cylinders magnetised in the direction of their axes. Their results, taken in connection with those of Schneebeli and Helmholtz, agree in showing that the effective poles of a magnet are about one-twelfth of the distance of the length from the ends. This result is, according to the observers, in all probability correct to within five per cent.

Light and the Electric Resistance of Metals.

Mr. Arthur E. Bostwick has made an elaborate series of experiments on the supposed influence of light in altering the resistance of metals. Since the diminution of resistance of selenium, when a ray of light falls upon it, was discovered by Messrs. May and Willoughby Smith, Dr. Richard Börnstein has attempted to show that not only selenium and tellurium possess the property in question, but other metals such as gold, silver, platinum, also possess it. This effect was not verified by Siemens and Hausemann, of Berlin, and now Mr. Bostwick's researches have not established the fact asserted. His conclusion is that "if light causes any diminution in the electrical resistance of metals, it probably does not exceed a few thousandths of one per cent."

A Tell-Tale Electric Bell.

In order that the person ringing an electric bell may be able to tell whether, on making contact, the bell actually rings, Mr. Douglas Mackenzie has devised the following arrangement. Besides the press-button, and let into the wall, is a simple telephone receiver of the Elisha Gray or Bell model, and consisting of an electro-magnet with a soft iron plate armature free to vibrate over one of its poles. The sounding or "clicking" core of Page may also be employed instead of the diaphragm armature. This electro-magnet is formed up in circuit with the bell and battery, so that when the bell is in action, with its contact interrupting the current, the telephone or electro-magnet will emit a musical note or hum, which, when heard by the person ringing the bell, informs him that the bell is ringing, always supposing that the current is strong enough.

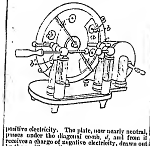
THE TOEPLER-HOLTZ ELECTRICAL MACHINE.

The following description of the Toepler-Holtz machine is given by Mr. H. W. Eaton in *Science*:—

Consider the machine before you, the revolving plate in front. Designate the right-hand paper sector by *a*, the brush connected with it by *b*, the comb connected with the discharging-rod by *c*, the comb in metallic connection with a similar comb diagonally opposite by *d*, and the corresponding parts on the left-hand side by *a'*, *b'*, *c'*, and *d'*. If the left-hand sector, *a'*, be charged with negative electricity, it draws positive electricity from the comb *d'* upon the revolving-plate, which is supposed to move in the direction of the hands of a watch. When the positive electricity on the plate reaches the brush *b*, it draws negative electricity from the brush, and leaves the sector, *a*, charged with positive. This positive electricity on the sector, and the positive that is left on the plate, both draw negative from the comb *c*, and leave the discharging-rod connected with it charged with



positive electricity. The plate, now nearly neutral, passes under the diagonal comb, *d*, and from it receives a charge of negative electricity, drawn out by the positive on the sector, *a*, which at the same repels positive electricity along the diagonal, and out of *d'* upon the revolving-plate. The plate, now charged with negative electricity, passes under the brush *b'*, draws positive electricity from it, and thus increases the negative charge on the sector, *a'*. The residue of negative electricity on the plate, and the negative on the sector, both draw positive from the comb *c'*, and leave the discharging-rod connected with it charged with negative electricity. The plate, now nearly neutral, passes to our starting-point, *d'*, and the process is repeated. If the machine is operated in the dark, the brush, *b'*, and the points on *c'* and *d'*, will be tipped with the well-known positive brushes, while *b*, *c*, and *d* will show only the negative glowing points. The relative lengths of the brushes on *c'* and *d'* will depend on the position of the discharging-rods. If *a* is negative in the place of *a'*, the position of the brushes will, of course, be reversed. The nature of the electricity on any part of the machine may be tested by bringing the point of a lead pencil near it, and noticing the form of the discharge from the point.

The great use of the knobs on the revolving-plate is to keep the paper sectors charged. Two knobs give better results than the usual six or eight; the reason apparently being, that the larger number of knobs keep the sectors overcharged, and there is a continual loss (by brushes from the sectors) of electricity that would otherwise remain on the revolving-plate, and help to increase the charge on the discharging-rods.

Somewhat longer sparks are also obtained by connecting the sectors and discharging-rods on the same side by conductors; but the machine, thus arranged, reverses more readily, does not give sparks so rapidly when the discharging knobs are near together, and is started by separating the knobs.

In some forms of the machine used in Germany the fixed plate is in two parts, separated by a vertical air-space. This is an improvement, because it prevents the electricities of the two sectors from uniting across the surface of the plate. Machines of this sort sometimes have as many as sixty revolving-plates, all on one axis. Such machines give large quantities of electricity, but not very long sparks.

The following experiments, not generally known, illustrate the power of the single-plate machine. If a strip of vulcanite about two inches wide is moved to and fro in front of the positive pole, the length of the spark will be greatly increased, sometimes reaching five inches and a half on a machine whose revolving-plate is only ten inches and a half in diameter. If a drop of stearine is placed on a thin sheet of glass, which is too large for the spark to pass around the edges, and the glass is held between the discharging-knobs of a good ten and a half inch machine, with the drop toward the positive knob, the spark will pierce the glass when the knobs are about one inch apart.

Competitive Trial of Electric Launches.—A company of seven in the Electricity, including Mr. Courtenay, managing director of the Storage Company, Mr. Simpson, representative of Messrs. Siemens, Mr. Thornton, and others; a company of eight in the Australia with Mr. Stephens, Lieutenant Robinson, R.N., H.M.S. Vernon, Mr. A. Reckenzaun, and others started from Millwall at 1.55 on Saturday last, arriving at Charing Cross at 2.32, the Australia leading. The Reckenzaun motor on board the Australia took a current of 37 ampères with 100 volts. The Siemens O_2 propelling the Electricity consumed 47 ampères with 80 volts, but the accumulators of the Electricity were heavier than those on the Australia. The boats returned from Charing Cross at 2.10, made two stoppages of about ten minutes each, and arrived at Greenwich pier at 4.10 p.m. Both launches cruised about until six o'clock, when they were docked at Millwall on the Storage Company's wharf. The proceedings were very successful, and the whole party, consisting of some twenty-four gentlemen, some of whom were on the steam launch, expressed their admiration and congratulations. The cost of the Australia complete is 200*l*.

Engineering

Sept 26/84

starting-point, was not placed high enough. It appeared that the Carrels, neglecting their instructions, had made a push towards the summit, but had reached a height of only about 19,000 feet. As they were quite unencumbered, carrying no instruments, and only enough food for their own use, and had no traveller to look after, and yet came back quite exhausted, it was obvious that we should have to get still higher up before we could make a serious effort to reach the summit. So, as soon as he was well enough, I sent Louis with Perring down to the first camp to fetch up a tent, which had been left there, and when this arrived we were in a position to go forward again.

"On the following morning I went myself up the ridge to look for a higher camping place, and found one on the eastern side on some broken rocks, at a height of 17,400 feet. By this time I was in rather better condition than the Carrels. Feverishness had disappeared, and my blood had resumed its normal temperature. The gaspings had entirely ceased, and headache had gone. You will perhaps inquire how I knew that I was feverish; for in regard to this matter one is often mistaken, and fever is supposed when it does not exist. By the advice of the distinguished physician whose name has been already mentioned, Dr. Marcet, I had provided myself with a registering clinical thermometer for the purpose of taking blood temperature at great elevations. This was duly done, and in respect to this matter nothing more need be said than that at our greatest heights the temperature of the blood was (just as it is at the level of the sea) higher during periods of warmth, and lower when it was unusually cold; but stood at its normal height, when the thermometer was at 60° or thereabouts, and did not appear to be affected by low atmospheric pressure at all. In recommending me to take this little instrument (which I have in my hand), Dr. Marcet rendered me a great service; and amongst all the devices and instruments which have been pressed upon the attention of travellers in general, of late years, I know nothing equal to it in importance. By constant observation, I was able to detect the earliest advances of fever; and by taking proper steps in time, was able to get through the entire journey without having an attack of fever worth mentioning. Its expense is trifling, and it can easily be carried in the waistcoat pocket. When we were first laid on our backs by mountain sickness, it showed that my blood temperature mounted to 100°·4, but by the end of the year it had fallen to its usual height, viz., 98°. Still, although the more disagreeable symptoms had gone, we found ourselves remaining comparatively lifeless and feeble, with a strong disposition to sit down when we ought to have been moving." * *

Mr. Whymper then described his first ascent of Chimborazo, and concluded his account of this mountain by saying, "My residence on Chimborazo thus extended over seventeen days. One night was passed at a height of 14,400 feet, ten at a height of 16,500 feet, and six at 17,300 feet. During this time, besides ascending to the summit, I also went three times as high as 18,500 feet. When we quitted the mountain, *all trace of mountain sickness had disappeared*, nor did it touch us again until we arrived at the summit of Cotopaxi. * * *

"The height of Cotopaxi is 19,600 feet. Our camp was placed about 130 feet below the loftiest point, and it was the most elevated position at which any of us had ever slept. We remained there twenty-six consecutive hours, feeling slightly at first the effects of low pressure, having the same symptoms as we had noticed on Chimborazo; and we used chlorate of potash again with good effect. All signs of mountain sickness had passed away before we commenced the descent, and *they did not recur again during the journey*. * * * * *

"This, ladies and gentlemen, nearly brings my remarks to a close, and, in conclusion, permit me to say a word more in respect to mountain exploration in general. Amongst certain persons it is still fashionable to affect a description of scorn, bordering on contempt, for anything in connection with mountains and mountain work. None of us feel, perhaps, very deeply the criticism of those who are evidently ignorant of the subjects on which they talk; and, in this matter, speaking for myself, I rather look forward to the time, which will surely come, when the study of mountains, the ascent of mountains, and even prolonged residence on mountains, will be found essential for the prosecution of a score of sciences. Before this could be carried out, it was necessary to learn whether life could be made endurable at great heights. We were always haunted by the fear of an invisible enemy who might strike us down at any moment. What we wanted to know was, not whether life could exist at a height of 20,000 feet (that was settled seventy-five years ago, by Lussac), but whether man could become so far habituated to the low pressure which is experienced at that height, as to be able to live without inconvenience, and to do useful work. I went to the Andes in search of an answer to these questions, you have heard the story, and can form an opinion whether it affords encouragement for the prosecution of exploration in other quarters."

ON SOME POINTS RELATING TO THE DYNAMICS OF "RADIANT MATTER"

As the important researches of Mr. Crookes may be said to have made the evidence of the molecular state of matter (grounded on indirect reasoning) almost ocularly visible—the mechanics of gaseous matter therefore acquires a fresh interest. As some years back the present writer devoted much thought to the clear realisation of the nature of the motions of the molecules of gases in connection with a proposed explanation of the mode of propagation of sound on the basis of the kinetic theory (published in the *Philosophical Magazine* for June, 1877), it then appeared to him that the systematic *regularity* of the motions of the molecules of gases was not in practice so generally appreciated as it might be; although of course the mathematical basis of the subject was well established. It has been not unusual to speak of the extreme "irregularity" of the normal motions of gaseous molecules—which is undoubtedly true of any molecule taken individually. The comparison of the molecules of a gas to a "swarm of bees" (sometimes adopted), though no doubt highly convenient and useful to aid the conceptions in some respects, has probably gone to support (rather than not) the idea of a kind of confusion in the motions of the constituent molecules of gases; whereby the systematic *regularity* (or symmetry of the motion) tends to be left out of view. This will perhaps appear more evident if I state the following proposition in regard to a gas, which is only a direct corollary from the established mathematical principles—true in every state of the gas, but emphasised by rarefaction.

The normal motion of the molecules of a gas takes place in such a way, that every point in the gas is a "radiant point," such that matter passes to and from that point (to a certain distance) in the direction of rays: i.e. *as if a luminous point were situated at the point in question*. Or more generally put: If finely subdivided matter be in motion in space according to its own dynamics, every point of space becomes a radiant point; the extent of the radiation of matter depending on its fineness (other things being equal).

It is, I believe, the losing sight of the systematic regularity (or symmetry) of the motion of the molecules of a gas in its normal state, which (as it would seem, at least) has caused the connection of gaseous motion with the conditions for gravity to be overlooked—or the fact to escape realisation that on rarefying the gas, this symmetry of motion (existing in the normal state of the gas) gradu-

THE LARGEST ELECTRICAL INFLUENCE MACHINE IN THE WORLD.

THERE has just been completed for the physical laboratory at South Kensington, the largest electrical influence machine in the world. It is made on the now well-known pattern of the Wimshurst machine, and was constructed by Mr. Wimshurst himself for the laboratory at cost price. The discs are 7ft. in diameter, of plate-glass, ⅜in. thick, and weigh 280lb. each. They are pierced with a central hole 6½in. in diameter, and are firmly attached to gun-metal bosses 15in. long, which run freely on an iron tube 3in. in diameter. This tube is supported by A frames of oak, having heavy gun-metal caps so shaped as to afford a support for the iron tube and ebonite rod to which the collecting combs and discharging terminals are attached. The "neutralising" rods of brass, with their fine wire brushes, are attached to the projecting ends of the iron tube, while the pulleys are firmly secured to the outer ends of the gun-metal bosses. The discs, which are varnished with shellac dissolved in alcohol, have each 16 radial sectors of tinfoil 19in. long, with a mean width of 1·05in., thus having an area of 31·35 square inches each, or a total metallic surface on each plate of more than 500 square inches. The collecting combs are connected to the discharging terminals by interchangeable brass rods, bent or straight, so that the position of the combs with respect to the horizontal diameter of the discs can be varied within about a 10in. range, that is 5in. above and below a line representing the horizontal diameter of the plate. The discharging rods are of 1¼in. brass tubing, and are fitted with interchangeable brass balls of different diameters. The distance apart of these balls can be varied by turning the glass handles at the other end of the discharging rods, which are made to revolve around a vertical axis, so that the terminals can be separated by any desired distance. At the time of writing, we believe, the machine has not been tried under favourable conditions; but in the workshop, surrounded with a variety of metallic conductors, and in an atmosphere rendered rather damp by the escape of steam from a boiler and engine at work, it started at once, and maintained a constant stream of sparks 14in. in length—a performance which will no doubt be improved when, under the care of Prof. Guthrie, it is fully tested in the laboratory at South Kensington.

Engineering Feb. 13/85

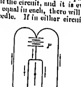
ELECTRIC GAS LIGHTERS.

At the International Society of Electricians, M. Napoli submitted, on behalf of M. Arnaux, a number of electric lighters all based on the same principle. The principal organ is a tube, about the size of an ordinary lamp chimney, in which is placed a stick of carbon of the same length as the tube, a bar of zinc, one-third the length, and an exciting liquid which when the instrument is vertical does not touch the zinc. By reversing the apparatus, a current is generated which is used either to redden a thin platinum wire, or produce a succession of sparks between two terminals. Another instrument by the same maker, is employed to detect gas escapes. It consists of a similar reversing battery, and a supplementary part in which is a platinum wire inclosed within a fine wire gauze envelope, the line being brought to red heat by the current. In the event of a gas escape, the temperature of the wire is increased, and by a somewhat complicated system a signal bell is set ringing.

Engineering – Feb. 13/85

THE INTERNATIONAL SOCIETY OF ELECTRICIANS.

Several interesting papers were read at the recent meeting of the International Society of Electricians, held at Paris on the 4th inst. One referred to a so-called Micrahmeter, devised by M. Maiche, for the measurement of small resistances. The accompanying diagram will give a clear idea of the instrument, which was made by M. Carpentier. The circuit of a battery P is divided into two parts as shown. A suspended magnet A is placed between the branches of the circuit, and it is evident that if the current is equal in each, there will be no deviation of the needle. If in either circuit a resistance



of unknown value is introduced, it will produce a deflection which may be counterbalanced by introducing in the other circuit a series of known resistances, until the total equals the unknown resistance. Or the same result can be obtained by gradually removing the wire which affects the needle; indeed the principle of the apparatus is based on this method. The circuits are replaced by coils, and the displacement of one of them gives upon a graduated scale the measure of the resistance sought. This little instrument, which is simple, cheap, and easily used, measures extremely small differences of resistance.

Engineering. Feb. 13/85

ELECTRICAL SURGERY.

M. Chéroy submitted to the Académie des Sciences during its séance of February 3 a new cauteriser fed by secondary batteries. A great difficulty attending the use of such an instrument, especially in localities where surgeons have not a dynamo at their disposition, lies in the charging of the accumulators. M. Chéroy proposes to effect this either by the use of a hydro-electric battery, or, where lighting gas is available, by means of a thermo-electric pile. In the first case he employs a vert-de-gris battery, without a porous cell with zinc plates. The electromotive force of the accumulators being 2 volts, the battery is so arranged as to have 2½ volts, and to give a flow of six ampère hours. From sixteen to twenty-four hours are required for charging. In the second case the battery is composed of ninety thermo-electric elements working by gas or probably by petroleum. The constants are 4 to 5 volts and 4 to 6 ampères.

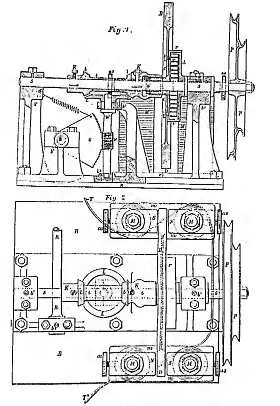

Fig. 2

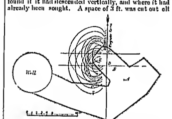
accident. The essential condition is that the pontoon shall rise with its upper surface perfectly horizontal, whether the load be exactly in the centre or not, and shall maintain its position as the car is moved along it, and while the weight is being transferred from the centre to the end, and is finally removed to the shore. In the engraving the pontoon is shown in its highest position, and the dock is represented by a wrought-iron tank partly decked at either side, and thus hiding a part of the pontoon. The deck is cut away in two places to allow the towers to pass through it. These towers are of such a length that the machinery they bear on their summits never descends below the level of the dock wall. They carry a set of hydraulic pumps which are connected by pipes with a system of hydraulic presses mounted on an intermediate deck of the pontoon about 6 ft. below the upper surface. The rams of these presses are visible in the figure, and are seen to be arranged in seven longitudinal rows. They are also disposed in rows crosswise, the central rows comprising seven presses, and those nearer the ends five and three presses respectively, while at the extreme ends there is only one longitudinal row, and consequently the cross rows become single presses. The aggregate area of the rams in each cross row, whether it contain one, three, five, or seven presses, is always the same, and as they are all exposed to the same water pressure per square inch, it follows that the lifting action per unit of length of the ship is equal. Of course a vessel does not weigh an equal amount per foot run from end to end, but her girder-like form is well capable of transmitting a part of the load amidships to the bows and the stern. In lifting the vessel, the pressure of the rams is transmitted through columns fitted with keel and bilge blocks, as will be explained when we come to the car. All the presses are connected to the same pipe, which affords communication with the pump in the tower, and thus the pontoon can rise and fall without in any way interfering with the action of the rams. Provision is made also for arranging the presses in groups if desired, and transmitting a different pressure to each group.

The pontoon is made to rise and fall quite vertically by the four sets of hydraulic rams shown at the corners of the docks. Each set consists of two cylinders and two rams, the cylinders being fixed to the dock wall, and the rams to the pontoon. One cylinder is inverted and projects upwards, working over a ram standing upon the deck of the pontoon, while the other cylinder hangs downwards, and has its ram connected to the pontoon by two side rods. The cylinders at the diagonally opposite corners are connected together in pairs, the inverted cylinder being coupled to the upright cylinder and vice versâ. The whole system is filled with water, and a moment's consideration will show that the water forced out of one press must be received in the corresponding one, and that this is only possible when the plungers move at similar rates. Supposing that, as the pontoon stands in the engraving, 100 tons were piled at one end. That end would immediately begin to sink, but in doing so it would force water out of the two upright presses into the two inverted presses at the opposite ends, and the other extremity of the pontoon would be pressed down at exactly the same speed as the loaded part. Such a case assumes the structure to be floating idly with no reserve of buoyancy, a condition in which it would be manifestly impossible to run a heavily laden car upon it. In actual work it is guided in its rise and fall by large pillars acting as anchor rods, and when it has attained the proper level these rods prevent any further rise. The pumping is then continued until the pontoon is sufficiently buoyant to receive its full load without sinking at all, and then the only influence of an unequally distributed weight is to create a hydraulic pressure which holds down the opposite end of the structure and keeps the whole horizontal.

(*To be continued.*)

FINDING A BORE HOLE.

IN sinking a well at the Holyrood Brewery of Messrs. William Younger and Co., Edinburgh, it was considered necessary, after the bore hole had gone down 200 ft., to connect it by a mine with a neighbouring well 18 ft. 3 in. distant, centre to centre. The miner was entrusted with the work, but, owing to one of his plumb-lines not hanging vertically, he cut his gallery in the wrong direction and failed to find the bore hole. A mining engineer was then sent down, and he showed where the hole ought to have been, but as it was not to be found at that spot, it was evident that it had diverged from the vertical. The ground had already been cut away all round the place, and an unsuccessful attempt had been made to locate the hole by the device of listening while the rods were shaken within it. It therefore appeared that large quantities of ground might have to be excavated before the hole could be found. At this point Mr. Andrew Haddow, engineer to Messrs. Younger and Co., took up the question, and located the hole by an extremely ingenious and, we believe, perfectly novel device. Referring to the accompanying engraving, A represents the place where the bore would have been found if it had descended vertically, and where it had already been sought. A space of 3 ft. was cut out all



round this spot, and the mine extended 6 ft. further before Mr. Haddow attempted to indicate the position of the hole by the happy device of passing a magnet down it, and noting its effect on a compass stationed in the mine. He procured four 8 in. bar magnets, which he put end to end and secured between two laths of wood. These were lowered into the bore with the south pole downwards. The north end of the compass needle moved first to the west, then to the east of zero, which showed that the magnets were on the west side of the compass, and led to the mine B being cut. While this was proceeding Mr. Haddow set the compass on a table and passed the magnet round it; finding a number of points on the floor where the deflection of the needle equalled ½ deg., he then drew a line through the points found. He did the same for other deflections and thus produced a series of curves. The compass was then stationed at the points C and D in the mine and the deflections noted. The points C D were marked on the plan and a tracing of the magnetic curves set over each point as shown. The observed deflection at C was 3⅞ deg., and at D, 6½ deg. The bore E was found where the curves corresponding to these deflections crossed one another, being about 8 ft. from the expected position.

JAMIESON'S ELECTRICAL GOVERNOR.

IN a paper lately read by Mr. Andrew Jamieson before the Institution of Civil Engineers, he laid it down that a primary requisite in electric lighting was a good electrical governor, which should automatically open and close the throttle valve in synchronism with the load or work to be done, and leave the valve in its last position until there was a change in the load, or in the steam pressure, in order to prevent the breaking of lamps or variations in their light, owing to bad governance or ill-attention to the engine.

Mr. Jamieson exhibited a governor which in conjunction with Mr. Stephen Alley he had devised and tried with good results on board the s.s. Thistle, at Glasgow. It is based on the phenomenon exhibited in Arago's disc, and consists of a copper disc revolving between the poles of an electro-magnet and actuating

Iron June 83

ELECTRICITY APPLIED TO FIREARMS.—A Frenchman, M. Clair, has invented an electric rifle, which is to be exhibited at Amsterdam. It is not the case that an electric shock takes the place of an explosion of powder; only that the electric spark is made to supersede trigger, hammer, and cap, and ignite the powder. The rifle is a breech-loader, and the cartridge is of metal. Instead of the cap, there is a copper wire passing through a metallic eyelet-hole in the wad, which eyelet-hole is put in electrical connection with a small hook by means of an inch or two of platinum wire. On pressing a button, which does not interfere with the aim so much as pulling even a hair trigger, the electric current, derived from a small accumulator in the stock, passes from the metallic eyelet-hole into the platinum wire, which it raises to incandescence, igniting the powder at the front end, and thus giving a great mechanical advantage. This is not all. The same barrel may contain two or more cartridges, which are fired successively in the following manner: the platinum wire of the cartridge nearest the breech is slightly larger in diameter than the next, this one larger than the succeeding, &c. The consequence is that the same current first makes the thinnest wire red hot, then that which is slightly thicker, and so on until all are fired.

Iron June 83.

THE CAPACITY OF ACCUMULATORS.—The Paris correspondent of *Nature* writes:—An interesting experiment took place on June 24, at the early hour of 3.45 in Paris, for the purpose of testing the capacity of accumulators of the French Storage Company to move tramcars. We travelled up to La Muette and back, a distance of 30 kilometres, in about three hours and twenty minutes, including stoppages and loss of time incurred by several incidents. The road has many steep inclines, which were ascended without difficulty. The mean velocity exceeded 10 kilometres per hour. The electricity was supplied by seventy accumulators, weighing 30 kilograms each, which were placed under the seats. At starting the potential was 140 volts, and having completed its task the current was as high as 126, so that at least 10 kilometres more could have been run if deemed necessary. This run is the longest on record made by electricity. M. Philippart was directing the operations.

THE PRACTICAL APPLICATION OF ELECTRICITY.—The National Museum at Washington is one of the best examples in the United States of the practical application of electricity. In so large a building, says *Nature*, it was found advisable to take advantage of the best means of communication, first being its system of telephones and call-bells, by which those in any room can communicate with every room in the building. Twenty-six telephones are connected by a local telephone exchange, which in turn is connected with the main telephone office of the city. The result is that but three messengers are needed in this vast establishment. The photographic laboratory is independent of the sun, owing to the electric light there used. If one of the 850 windows or 230 doors is opened, a bell rings, and an electric annunciator shows to an attendant at the main office which window or door it is. This system is soon to be applied to every case of specimens. The watchmen at night, also, are kept to their posts by hourly releasing an electric current at certain stations, which pierces a dial and records their visit. The sixteen clock dials are likewise run by electric currents.

Iron, June 29th '83.

RAILWAY SIGNALLING.—At the Society of Telegraph Engineers and of Electricians a paper was read on February 22, by Mr. R. von Fischer-Treuenfeld on the Siemens railway gong alarm, which is now adopted in France, Belgium, and other countries, for railway signalling instead of the block system so largely employed in this country. With this apparatus, which is worked by magneto-electric currents generated by the signalman in turning a handle, the signals are given by the strokes of a large bell. It was, however, agreed by Mr. Spagnoletti, Mr. W. H. Preece, and the author, that the gong alarm is not so well adapted for our busy English railways as the continental ones; but it was thought worthy the attention of colonial railway engineers and the managers of local lines on which there was but little traffic. The exigencies of English travelling demanded a system which appealed to the eye as well as to the ear, so that there would be no risk of the signalman forgetting what the signal was, since he could refer to the visual sign. Several speakers insisted strongly on the necessity of a uniform code of signals for railway working throughout this country. At present on some lines the "danger signal" is one stoke of the bell, and on others the "line clear" signal is one stroke of the bell—a state of things which might sooner or later lead to accidents, especially in the case of a signalman who had changed service from one of the former companies to one of the latter. Professor Ayrton also advocated the revival of magneto-electric generators instead of batteries for railway signalling and telegraphic purposes. He had recently found from experiment that a magneto-electric machine turned by hand gave a far stronger current than that used in telegraphing; and he pointed out that ordinarily small dynamo-electric machines could be used in a similar manner.

Electrical Review
May 9, 1885

* * An electric tooth-pulling machine, which is quick and almost painless in its operations, is said to pull seven teeth in five seconds. A pair of forceps protrude from a nickel tube which is connected with a wire. The forceps are applied to the tooth, the operator touches a spring, a spiral arrangement within the tube winds up in a twink, draws down the forceps like a flash, and in an instant the tooth is jerked from the jaw and cast on the floor.

London - Work Law Express
April 20/85.

MAKING BUTTER BY ELECTRICITY.—If the announcement made by a French contemporary remains true in practice, butter-churn makers will perhaps have to turn their attention to the construction of other things; perhaps dynamo-electric machines of very low electro-motive force. According to a patent taken out by Mr. A. C. Tichenor, milk is introduced into a vessel of special form, and into it are placed a pair of electrodes, and a current is thus passed through the milk. Butter is formed in little balls on one of the electrodes, and it is said that to extract the butter from forty-five litres of milk the current from a dynamo-electric machine equivalent to that of about forty Daniells for from three to five minutes is all that is required. With such a current the balls of butter are sufficiently voluminous to detach themselves from the electrode and float to the surface of the milk. The butter thus obtained has to be worked in a baratte or something of the kind, so as to work the small pieces into a compact mass. The patent also mentions the electric manufacture of cheese and of removing the bad taste of butter that has turned mould. We do not know how far the indications of the patent specification have been verified.—

ELECTRICAL CURIOSITIES.

Odd Instruments to be Seen Among Dealers in Telegraphic and Electrical Supplies.

"Among the interesting articles that we sell," said a dealer in telegraphic and electrical supplies, "is an improved counting machine. It is a very useful appliance for superintendents, telegraph inspectors and others connected with telegraph construction and repair work. It is a curious instrument and is about the size and shape of a watch. Carried in the hand a single pressure upon a spring that it contains, records one and so on up to 1,000. It is used for keeping tally of any kind, such as counting poles, broken insulation, making inspection tallies of materials, etc.

"A curious name to an important little article is The Anti-Hum. The multiplication of telegraph lines and their connection with buildings of all kind has made a demand for some device for stopping the humming noise. The principle of this instrument is simple. An ordinary shackle of galvanized iron is provided with a washer or cushion of soft rubber, which, when connected, takes the strain off the wire, stopping its vibration, which is the cause of the noise. A loop of wire around the instrument conveys the current.

An instrument of peculiar interest is an electro-mechanical tower bellstriker. It is adapted to strike by electrical connection large bells of from 500 to 10,000 pounds weight. It will operate with a light battery power, and all that is required in connection with it is a simple key or press-button and battery. It is used for fire alarm purposes in connection with the telephone exchanges. As in many cases the telephone is used for sounding fire alarms, the operator can with this apparatus give the public alarm on any near tower bell by the simple use of his press button.

"An electric apparatus for blasting is something novel to the general public, although it has been in use some time. It is a magneto-electric instrument of small size and weighs only about sixteen pounds. It occupies considerably less than one-half a cubic foot of space. It has a magnet of the horse-shoe character, of iron, wound about with coils of insulated copper wire; between the poles of the magnet there is fitted to revolve an armature of cylindrical construction, carrying in its body other insulated wire coiled longitudinally as to the cylinder. The rapid revolution of the armature by suitable means generates and sustains in the machine an accumulative current of voltaic electricity of great power, which at the moment of its maximum intensity is practically switched off to the outside circuit in which are the fuses, and in the interior of each fuse the ignition is accomplished instantly. It was a machine of similar description that was used in blasting at Hell Gate when Gen. Newton's little daughter pressed the button that set the apparatus in motion by which thousands of tons of rock were displaced."

Phila. Ledger

ELECTRICAL CARTAGE.

In the early days of telegraphy a standard joke repeated in various forms related to the man who expected his messages, or his boots, to be strung upon the telegraph wire and carried bodily to their destination. That joke as such is now out of date, for it is possible, by means of Prof. Jenkin's system of "Telpherage," to actually send a pair of boots by wire from one place to another. The system has been in experimental use in England for a year or more, and the "Telpherage" Company recently equipped a line which is to be put in practical use at a South American mine. "Telpherage" is a manufactured word intended to designate all modes of transport effected automatically with the aid of electricity. But as limited to Mr. Jenkin's invention it means a system of electrical *cartage*, at a slow pace, of minerals and similar materials that can be divided into packages of two or three hundred weight. The conducting line is a single suspended wire or rod, but as it also sustains the weight of the train, it has to be strong enough to carry the traffic. There is also a return line, and the two are so arranged in cross-over sections that whenever a train bridges the sections the current from the dynamo at the end of the line passes through and sets in action the motor of the train, which is one of the ordinary forms of electric motor. The "trains," of sufficient length to bridge over the gap between sections, are made up of buckets or other suitable receptacles for coal, grain or minerals, these buckets being suspended on wheel trucks running on the line wire. When the train is made up and the current is passed through the motor the latter drags the train along the line. As Professor Jenkin designed the system to be a substitute for cartage, the speed is only four or five miles an hour. The problems involved are chiefly mechanical, most of the electrical difficulties having been already overcome in apparatus used for other purposes.

At first sight it would seem to be a very wasteful way of using power, but the losses by conversion are made up in other ways and on its limited field telpherage appears to be of economical value. In a line five miles long with twenty-five trains, each conveying a useful load of fifteen hundred-weight, the estimated cost of cartage is about five cents per ton per mile. In a shorter line with fewer trains the cost is somewhat increased, reaching perhaps six cents per ton per mile. At such rates it cannot compete with railroad transportation, nor is it expected to do so. Its rival is cartage, and the estimated cost of cartage (leaving the roads out of consideration) is twenty-five cents per ton per mile. In these calculations it is assumed that the useful power exerted at the locomotive is only one-third that of the stationary engine, the loss of two-thirds of the power arising in the conversion of mechanical power into electricity in its reconversion and in electrical resistances. Better results than this can no doubt be reached, but telpherage appears to already offer a cheap means of cartage in some situations, notwithstanding this great waste of energy.

The uses of such a system of conveying goods are various, especially in localities without roads. The lines can be cheaply constructed to mines, and may be tapped wherever desired to obtain sources of power for operating circular saws or electric light plants. Or, in the mines themselves, the telpherage lines could be employed to carry the coal or minerals to the mouth at small cost, while at the same time furnishing electricity for lighting the mine. This is a field of work entirely distinct from that of the ordinary electric railway, which is almost as costly in construction as a steam railroad, and is designed to carry both goods and passengers at a high speed. The telpherage lines designed by Professor Jenkin may become feeders to, but not the rivals of, railroads. They can compete with mules and horses at points where steam railroads cannot be used.

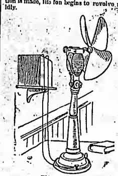
Good for Hot Weather.

An electric lamp manufacturing firm have recently invented something quite new. It is an electric fan. The illustration shows it. Given any sort of standard, plain or ornamental, like an ordinary lamp pedestal and about a foot high. Upon the top is mounted a screw propeller fan. One who looks at this fan will see a small model of the screws which move steamers. The standard is of wood or other non-conducting material, with wires running up through the center. Wires from a small battery are connected with these near the bottom. When the connection is made, the fan begins to revolve rapidly.



ELECTRIC FAN.

The battery is contained in a little box four to five inches square. It holds material to generate electricity enough to turn the fan several hours. The fan is fixed upon a hinge, so that it can be set at any desired angle, thus changing its direction. Clockwork fans are not uncommon. In large factories, where numbers of men are crowded together in hot rooms, large revolving wooden fans are attached to the machinery and worked by steam. But this neat little electric arrangement seems an improvement on any other plan that has yet been tried.

FINISHING A TORPEDO.

At the Edison machine shops, No. 104 Goerck-street, the third of the electrical torpedoes in process of manufacture for the Government was finished yesterday. The torpedo is 45 feet long and 30 inches in diameter, and is made of polished copper. Its motive power is a small dynamo, which is inclosed in an iron case in the centre of the torpedo, and which operates a propeller. The torpedo will run 10 minutes at the rate of 10½ miles an hour, and is controlled by two wires connected with the shore. These are rolled up in an apartment in the torpedo and uncoil as it goes along. The contrivance is shaped like a cigar, pointed at both ends, and is suspended from a float. The boat moves on the surface of the water and the torpedo is 4 feet below. The charge is 350 pounds of dynamite. The torpedo will cost $5,000 and will demolish a million-dollar man-of-war. The Government will have eight of them.

HIGHLY DESTRUCTIVE TORPEDOES.

THE THIRD MADE BY EDISON TO BE SHIPPED TO-DAY—HOW THE THING WORKS.

The third of the five electrical torpedoes which are being built for the Government at the Edison Machine Works, No. 104 Goerck-st., has been finished and will be shipped to-day. These torpedoes, which are all made alike, are submarine vessels, consisting of a cigar-shaped copper hull—the torpedo proper—forty-five feet long and about two feet in diameter at the widest part, attached by upright steel stanchions to a copper float, which rises some six inches above the surface of the water. Placed fore and aft on the boat are two rods for showing signal flags, bells or lights. These rods are hinged at the base with a spring-hinge so as to assume an oblique or horizontal position when meeting and moving under an obstruction and to recover their position automatically when it is passed. Both hull and boat are protected from cables, ropes and other obstructions by a sharp steel blade, which runs from the bow of the hull to the top of the float and from the stern of the float to the stern of the hull and is set at such an angle as to make the torpedo dive under or cut through any obstacle. The hull or torpedo itself is made up in four parts or sections united by lock joints. The bow section contains the explosive charge, from 250 to 400 pounds of dynamite; the second compartment is filled with cable, which connects the torpedo with the shore and is paid out as the vessel proceeds on its errand; the third part contains the dynamo which supplies the power for propelling, guiding and exploding the torpedo; in the stern section are placed the steering apparatus and the shaft of the screw propeller.

The operator from his station on shore or on shipboard can at will start, stop or steer the dangerous craft and explode the charge, which can also be arranged to explode by contact if desired; and he receives notice when the hull meets with any obstruction, thus making sure of the proper moment for explosion. The torpedo weighs all told from 3,000 to 9,000 pounds according to the distance to be overcome, but no single part or section weighs more than 800 pounds. Fifteen minutes is all the time required to take it apart or put it together again. It will run ten minutes at the rate of ten and one-half miles an hour and it is claimed that it can demolish any man-of-war afloat. The torpedoes cost the Government, it is said, $9,000 apiece. Representatives of the English, French, Turkish and Japanese Governments have been inspecting them within the last few weeks with a view to ordering some made for themselves.

TORPEDOES FOR UNCLE SAM.

Built by Edison at a Cost of Five Thousand Dollars Each.

Although Congress did little toward preparing the country to defend itself against an enemy in case of war, the Navy Department has not been wholly idle, even outside of the preparing of plans for new war ships and completing the ships already begun when the present Administration came into power. Some time ago a contract was made with the Edison Machine Works in Goerck street to build eight torpedoes which should be propelled by an electrical apparatus and steered through wires from the shore or the ship from which they were launched. Three of these torpedoes have been completed and delivered. The picture gives a very excellent idea of what they are like.

The torpedo proper is 45 feet long over all. As shown in the cut, it is purposely made to appear thicker than it really is. It is cylindrical in the centre, tapering to sharp points at each end. It is thirty inches in diameter...

The explosive is put forward, the coil of wire through which the electrical current passes is in the middle, and the dynamo that turns the propeller and operates the rudder is aft. It is manifest that the device would not displace enough water to float itself, and a boat is therefore provided to float it. This boat is sharp at both ends and is decked over. It is modelled like a Yankee whaleboat. It is made of copper, as is the torpedo. Stiff but thin bars of iron connect and brace it firmly to the torpedo. These braces are put at an angle, so that if any obstructions, such as booms about a ship, are met the whole apparatus will dive under and continue on its course. A long slender guard projects aft under the propeller to protect it under like circumstances. The two balls that rest on top of slender rods above the float are to enable the launching party to keep track of and steer the craft. They are hinged in substantial springs, so that when diving under a log or other obstruction they will bend down into slots prepared for them and then rise up in place again. The contract provides that these torpedoes shall run not less than ten miles an hour. They carry 300 pounds of dynamite or any other high-power explosive. This quantity exploded against the side of a war ship is believed to be sufficient to annihilate somewhat those on board of her. The range of these torpedoes is limited to the length of wire they can carry. Those built so far carry enough to enable them to travel one mile and two-fifths away. The most astonishing curves and spirals can be made by them under the direction of the operator sitting at a table at the place of launching. They cost $5,000 each.

ELECTRICAL FLYING MACHINES.

Attempts in Germany and Russia to Make Balloons for Use in War.

BERLIN, July 27.—The success of the aeronaut L'Hoste and his companion in making in a balloon the journey across the Channel from Cherbourg to London has caused no little excitement here. It is the first successful attempt to reach a point determined on beforehand, and indicates a decided advance in aeronautics, which will be put to good use in a coming war. Germany and Russia have both for some time been pushing forward experiments in flying machines for use in war or otherwise. The direction in which they have been working was the one which, previous to the experiment just made by L'Hoste in the balloon Torcilleur, was most likely to be successful. It ignored the idea of the inflated gas-bag, which is enormous in size, difficult and costly to fill in war, and floats—a gigantic derelict—at the mercy of every current of air, a huge mark for the first gunner who can hit and bring it to the ground. Baumgarten in Germany and Baranovski in Russia have adopted the principle of the inclined plane pressed against the air, and thus capable of making some attempt, at least, to regulate its own course. In the kite the force that presses the inclined plane is the hand of the boy acting through the string. In the sail of the boat the resistance of the water to sidelong motion keeps the sail pressed against the wind. In the flying machines of Baumgarten and Baranovski the pressure is given by an engine carried by the machine and acting by means of fans. The difficulty was the weight of the engine and the fuel; but with the development of practical knowledge of electricity accumulators have been built which supply the maximum of motive power with the minimum of weight. If the attempts should prove successful, the problem of flying in still air would be solved. But whether man shall ever be able to ride the storm is another matter.

Rochester Herald. 9-17-86.

AN ELECTRIC BOAT.

The Volta is the name of a little electric boat which on Monday last crossed the English channel from Dover to Calais and back, a distance of twenty-four miles each way. She is thirty-seven feet long, seven feet beam and three and a half feet deep. Her propelling power consists of sixty-one electric accumulators, each eight inches square which were placed under the floor of the launch with a pair of Reckenzaun's electro-motors. The accumulators were charged two days before the electricity stored in them was used.

This little craft will carry forty passengers, but only seven, including a correspondent of the New York *Herald*, crossed the channel in her. She can travel at the rate of twelve miles an hour, though, of course, she is not driven constantly at that rate. The party left Dover at 10:40 A. M., reached Calais at 2:30 P. M. and arrived in Dover on the return a little after six o'clock in the evening, an average of about seven miles an hour, including the stop at Calais. The entire cost of the electricity stored in the accumulators was eight shillings, or two dollars, and that was sufficient to take the party across the channel and back. She ran easily, swiftly and silently, without smoke, noise or jar. The astonishment of those who saw the original steamboat, pushing her way through the water without sails, could not have been much greater than that of the persons who discovered the little Volta skimming over the channel without the sign of sails, smoke-stack, engine or boiler. Unquestionably electricity is the coming power for small boats, though until dynamos become more numerous and generally distributed those electric boats will have to confine their trips within the limits of stations where the batteries can be recharged.

It would appear from the success of the Volta and the statements of its owner regarding her speed and the cost of the electricity that great improvements have recently been made in storage batteries. As originally constructed they were not of much account except for laboratory illustration and experiment, but inventors have been at work on them right along with results that seem to be highly encouraging.

Brooklyn Eagle. 9-16-86.

The Voyage of the Volta.

In the race between aerostation and the development of electricity as a motor, the former had a start of nearly a century. Its progress has been slow, and it is doubtful whether it has even yet reached a stage of practical usefulness, although within the past year or two it has received an impetus in the land of its birth, which holds out a promise of better things to come. The success of two

47

aeronauts recently in directing their air ship from a point in France to another in London has given rise to the belief that with improved methods of applying electrical energy the balloon or aerostat of the not remote future will find its place among the established services of man, and that before the century closes the age of iron and steam will have given place to that of steel and electricity, while the upward progress of the race will be typified by the ascent of man into the air as a medium of transportation. It will be observed that electricity is actually the means by which this result is to be obtained, so far as we can see ahead, and yet, while steam will not be immediately connected with the enterprise, it will merely have been deposed one step as the servant of the electrician. The more ethereal energy will owe its life to the coarser, then as now, and will represent a refinement of power as much better adapted to the rarer wastes of the atmosphere as the bird with his hollow bones and spread of wing is a sublimation of the reptile from which he sprang.

Already the secondary battery, which is the electrical storehouse of energy, has been put to use in the aerostat; recently it was applied to the more material and onerous work of propelling a boat. In a sea so calm that sleeping gulls were not apprised of its noiseless approach, the cable tells us, the Volta was driven from Dover to Calais in 3 hours and 51 minutes and back again in 4 hours and 15 minutes, making the round trip of about 44 miles in a trifle over 8 hours, or at the not very startling rate of speed of about 5 1-4 miles an hour. Whether the inventors were pleased or disappointed with this experiment we are not told, but to persons who have seen the famous Herreschoff steam launch, Henrietta, dart like a dolphin through a lively seaway at the rate of 24 miles an hour, the result is not exactly startling. It is in the fact of electric propulsion, not in the measure of its achievement that success, if there was any in it, must be looked for. The one note of triumph to be detected in the account is the assurance that the secondary batteries were recharged but once during the entire trip. That is to say, with those batteries stored to their full capacity energy enough was developed to carry the Volta—dimensions not given—so many miles at such a rate of speed.

The Volta's is not by any means the first demonstration given of ability to propel small vessels by means of electricity, although it may be the first application of the mysterious and omnipresent force in an indirect way. Indeed, in a variety of ways, locomotion dependent upon a continuous current has been effected for some years past. Upon surface roads, for example, the supply of energy has been conveyed from the dynamo to the engine of a motor by means of the rails upon which it ran or by a wire in air. The Daft and Siemens systems represent these two methods, which have been differentiated in a number of ways. The secondary battery, however, for reasons that are easy to understand, has not yet been developed to yield a sufficient current for such ponderous purposes. The reader is probably familiar with the general principles of this discovery. A battery consisting of plates of metal, with the largest available area according to weight, is subjected, under chem-

ical treatment, to an electrical current, the effect of which is to produce rapid superficial decomposition. This decomposition represents the work of so much energy. When by reverse chemical treatment recomposition is effected, then the same energy, minus a little loss, is released in the form of electricity which is applicable to machinery. So far the current thus obtainable is bounded by the bulk of the metal treated. The secondary battery hitherto has been so heavy in proportion to the energy it stored that the force of gravity forbade its application, generally speaking, to other than static enterprizes. The value of the Volta's experiment lies, then, in developing a battery which could, without recharging, propel itself a given distance.

The demonstration at present is scientific, not practical. The economic side of the question is far more important than any that has yet been studied. The cost of generating an equal energy of electricity is so much greater than that of the steam which develops it as to forbid a substitution of one for the other for general purposes as yet. For particular purposes, such as submarine lighting, where gas would not serve; for submarine propulsion, where steam or other expansive gas would be out of the question, and for aerostation, where the maximum of energy and the minimum of weight are indispensable, electricity from a storage battery may have practical value. It has none yet.

THE ELECTRO-CHRONOGRAPH.

An Automatic Detective to Watch the Electric Lights—The Important Discovery of a New Orleans Mechanic Now Ready for Practical Demonstration.

Up to the present time the city has been compelled to depend upon the reports of the police force as to the number of electric lights which have been burning dimly, or left unlit during the entire night, or any portion thereof. Taking into consideration the extent of territory allotted to each man on the force, more especially in localities other than the more central portions of the city, these reports were necessarily incomplete, and it is presumed many lights, which were not burning at all, or only dimly so, escaped the notice of the police, and the city paid for lights that had not been furnished.

No device by which the length of time an electric light has been burning, or in other words no electro-chronograph has been heretofore known that could be practically applied to electric lamps in order to ascertain how long they may have been burning; but it remained for an ingenious New Orleans electrician and mechanic to solve the problem; and the result is that he has perfected an instrument which will not only answer the purposes for which it is intended, but he has also invented an automatic electric clock that will show the hours of the night from any street electric lamp in the city, and record the hour while the current is projected since each and every circuit of the different electric light plants in the city.

The first of these inventions, which was exhibited to the reporter last evening, was the meter. This is in reality an adaptation of the patent fire indicator to the purpose of measuring and indicating the time during which the electric lamp may be burning or not. The fire indicator is really a thermometer connected by wires with a battery and alarm bell. When the mercury rises to a certain height the metal comes in contact with brass, platinum or other conductive metal and completes the circuit, which sets in motion a vibrating electric gong and gives the alarm. This principle is reversed in the meter, and it is when the mercury in the thermometer falls that the circuit is closed and a small piece of machinery, devised somewhat after the plan of a watch, is set in motion and the time during which the light is very low, and consequently emits but little heat, or when it emits no heat at all, is indicated on the machinery. These indicators or meters, which can be constructed very cheaply, after the style of the Waterbury watch, are examined each morning by the police and can be then wound up, ready for service the next night. The thermometer is small, neat and compact and is to be so placed as not to interfere with the illuminating power of the light, or to cast a shadow.

A very small battery is all that is required, as sufficient electricity can be procured from a single Leclanche cell without deflecting more than an infinitesimally small quantity of the main current. The indicator or meter can be placed inside of buildings if required, connected as they will be by small wires.

The electric clock which this ingenious mechanic has invented, although involving no new principle, will without doubt prove of the greatest benefit to the citizens at large as well as remunerative to the inventor.

The hours of the day or night will be painted on the outside of the glass globes of the various electric lamps throughout the city, as on the dial of a clock. A small hole is drilled through the glass at the centre, through which will project the rod which will revolve the hands, which will be made of exceedingly light metal or wood. The rod forms the axis of a cog wheel which is geared by a series of wheels to the armature of a magnet. This magnet will move to and fro by a constant electrical current, automatically made and broke, as is the case in a vibrating gong such as are in general use on burglar alarms, hotel annunciators, etc. The rapidity with which this armature is to be moved can be adjusted by means of set screws, which can be moved wider apart to lessen the number of strokes per second, or closer together to increase the number, as may be required in regulating the time piece. The current which is to operate the clock is to be derived from the Electric Light company's wire, as in the case of the electro-chronograph before described, and as but very little is required the loss to the company will be small indeed from connecting with the small wires of the clock, the electro-chronograph being independent.

The motor of the clock is the electrical current applied to the armature, the motion of which revolves a cog wheel. Every time the armature is attracted to the magnet the wheel is moved forward one cog, and when the armature is drawn back by means of a small spring it is reset automatically and catches under the next cog, which is forced forward when the armature is again attracted to the magnet.

Both these instruments are supplied with their fusible wire automatic cut outs so that the delicate magnets and machinery cannot be injured by an excess of current, the thin wire fusing when the current becomes too strong.

Another advantage promised by the electric clock is in indicating the hour at which the current is projected over the wires. Thus, the company contract to light their lamps at 6 o'clock in the evening. The clocks are all set at that hour and the instant the dynamo commences to revolve the clock is started and continues as long as there is a medium of current on the wires. At 6 o'clock the lights are extinguished and the clocks cease working. When the hours for lighting and extinguishment are as above the clocks need not be reset in the morning, but should the hours of lighting be later the hands can be moved to the proper time each day by hand.

The clocks will not cost more than about $10 apiece, and at that rate, should the inventor's system be generally adopted—which it no doubt will be in every city where electric lights are in use—the fortune of the inventor is certainly made. The clock, he claims, is no infringement on the electric clocks recently introduced in this city, as they are operated from one central timepiece, which transmits a current each minute, while his clock runs automatically and by a constant current. The advantages of this electric clock are at once apparent, and will be highly appreciated by those whose duty or pleasure causes them to remain outdoors late at night.

Yesterday the inventor received information from the Patent Office at Washington, D. C., that his application and the caveat accompanying it had been examined and approved, and that a patent would be issued forthwith.

The inventor is in reduced circumstances, and for a number of years past has been devoting himself and his means to the perfection of a machine which proved to be a failure, and of which he would enter into no explanation. The name of the inventor, Prof. Edmunds, is well known in this city as a man of great talent and ingenuity. A working model of both the electro-chronograph and the clock were exhibited at his rooms at No. 138 Camp street, on the third floor, last evening, and both apparatus put to work by means of a battery composed of two Daniels cells.

To demonstrate the practical workings of the electro-chronograph he used a candle and moved it gradually away from the thermometer after having connected the battery. By degrees the mercury fell, and as soon as the light had been moved sufficiently far away the little watch commenced ticking, and continued to do so until the light was again moved close to the thermometer, when it suddenly ceased.

He has obtained one of the globes in use on the electric lamps in the city, and has had painted thereon the twelve hours of the day. He has attached his clock to this, and today proposes to apply to the Louisiana Electric Light and Brush Electric Light companies for permission to place this globe on one of their lamps.

He proposes to place his clock on the Louisiana electric lamp at the corner of Lafayette and Carondelet streets at 6 o'clock and allow it to remain until 6 o'clock this evening. He will then remove it to the Poydras Market and demonstrate its great utility on a Brush electric lamp. He will also attach the electro-chronograph and explain its use to any who may apply to him. There is not the least doubt of the success of these two valuable and ingenious inventions, and a man more deserving of a recognition of his attainments and merits could not be found anywhere.

A Note on the Sources

The pages which were microfilmed for this collection are in generally good condition in the original. There are some pages, however, which due to age are lighter than normal. Additionally, because some volumes are very large and have been bound tightly and cannot be unbound, there are intermittent occurrences of slight distortion of the edges of a small percentage of the pages. We have made every technical effort to ensure complete legibility of each and every page.
